RANDOMIZED MOTION PLANNING – A TUTORIAL

Stefano Carpin
International University Bremen, Germany, email: s.carpin@iu-bremen.de

Abstract

Sampling demonstrated to be the algorithmic key to efficiently solve many high dimensional motion planning problems. Information on the configuration space is acquired by generating samples and edges between them, which are stored in a suitable data structure. Following this paradigm, many different algorithmic techniques have been proposed, and some of them are now widely accepted as part of the standard literature in the field. The paper reviews some of the most influential proposals and ideas, providing indications on their practical and theoretical implications.

1 Introduction

Many fields beyond robotics, are benefiting from progresses in algorithmic motion planning. Examples include structural studies in biology, computer graphics, and computer assisted surgery among the others [44]. The successful application of these algorithms relies on the availability of an abstract formulation suitable to model many different real world applications, and on the ability to solve difficult instances in a reasonable time. Motion planning is performed as a search in a suitable space, called the configuration space. Early studies outlined that the basic version of this problem is PSPACE-complete [13],[60], and the best exact deterministic algorithm known is exponential in the dimension of the configuration space [12]. On the other hand, real world problems generate instances with high dimensional configuration spaces. Around the mid nineties a new approach was introduced, and this boosted the research in the field, as well as the practical use of these algorithms. This technique is based on the generation of samples to acquire information about the problem instance being solved. It has to be outlined that while the first algorithms heavily relied on random samples, there has been a recent trend to introduce also deterministic sampling schemas [46],[54], although this will not be covered in this paper. Samples are stored in a data structure which represents an approximation of the configuration space, as opposed to its exact combinatorial representation. The data structure is usually composed by nodes, i.e. samples in the configuration space, and links, i.e. valid paths connecting samples. Nodes and links can be stored in graphs or trees. The sampling based approach has some appealing properties. It is immediately applicable whenever a configuration state space is used to model a real world problem. For example, sampling based motion planners have been used for multi-robot systems [14],[65],[61], closed chain systems [20],[27],[68], and deformable objects [9],[42]. These algorithms are also well suited for practical parallel implementation [15],[16],[29], thus allowing further performance gains. Finally, the implementation of these algorithms is usually quite simple. The price to pay is completeness. Traditional combinatorial motion planning algorithms are complete, i.e. they will find a solution if one exists, and will report failure otherwise. Algorithms based on randomly generated samples obtain instead probabilistic completeness. This means that if a solution exists, the probability to find it converges to 1 when the computation time approaches infinity. So, if a path is not found it could be the case that a solution does not exist at all, or that the sampling process has not been able to get the information needed to solve the search. There have been also attempts to address the dual problem, i.e. to prove that a solution cannot exist [8]. However, while in principle this approach is appealing, it has not been shown to work under general conditions, and has not enjoyed great use up to now. In between the above mentioned forms of completeness, algorithms based on deterministic sequences achieve resolution completeness. This means that when the algorithm fails to find a solution, this implies that either the solution does not exist, or it requires a sampling resolution below the one used. This approach has been attracting some attention recently [17]. The randomized framework can be extended in many directions. This motivates the great number of different algorithms proposed up to now. Some algorithms and techniques proved to be very efficient and are now part of the standard literature in computational robotics. In addition to operative aspects, also the theoretical foundations of this approach have been addressed, so that some understanding about the power and the limitations of the framework has been obtained, although we are far from having a complete picture. This paper presents some of the most common algorithms, and give an overall perspective on the most widely used ideas in the field. For sake of completeness, we have to mention that the first broadly used motion planning algorithm incorporating random components has been
the so called Randomized potential field Path Planner (RPP) [7]. RPP uses a deterministic gradient descent strategy over a suitably defined potential field. When the planner gets stuck at in one of the possible local minima, a sequence of random motions of increasing length is activated, until the potential well is escaped. However, the RPP planner will not be addressed in the paper because the underlying mechanism is different, i.e. it does not generate samples to explore the configuration space, but only to recover from problematic situations.

The paper is organized as follows. Section 2 introduces the formal statement of the robot motion planning. Algorithms based on probabilistic roadmaps are discussed in the successive section. The basic formulation, as well as improvements, are illustrated and discussed. The section also provides the fundamental theoretical results concerning probabilistic convergence. Following the same approach, section 4 reviews algorithms whose underlying data structure is a tree rather than a graph. Finally, section 5 addresses practical issues related to the choice of a specific algorithm, while conclusions are offered in section 6.

## 2 Problem formulation

Extensive treatment of the basic computational aspects or robot motion planning can be found in [33],[43],[48],[62]. We here formalize the problem. The robot motion planning (RMP) problem is dealt with by using the configuration space approach introduced by Lozano-Perez [55]. Every robot is associated with a set of degrees of freedom which specify its placement in the workspace. The combination of the degrees of freedom assumes values in a space called the configuration space, usually indicated as \( C \). The configuration space is partitioned into two subsets, the space of free configurations, \( C_{\text{free}} \), and the space of obstacle configurations, \( C_{\text{obs}} \). The space of free configurations is the subset of valid configurations, i.e. configurations in which the robot does not collide with any obstacle and does not violate its mechanical constraints.

The space of obstacle configurations is its complement, i.e. \( C_{\text{obs}} = C \setminus C_{\text{free}} \). Given two points \( x_{\text{start}} \in C_{\text{free}} \) and \( x_{\text{goal}} \in C_{\text{free}} \), the RMP problem requires to compute a continuous function \( f : [0,1] \to C_{\text{free}} \), such that \( f(0) = x_{\text{start}} \) and \( f(1) = x_{\text{goal}} \). In general this function could even not exist, for example if \( C_{\text{free}} \) is disconnected and \( x_{\text{start}} \) and \( x_{\text{goal}} \) belong to different components. An ideal RMP algorithm should be able to determine this situation and stop the computation as soon as it is possible to establish that a solution cannot be found. As we will see, randomized algorithms fail to accomplish this goal, so it is common to bound the computation time in order to avoid infinite loops while trying to solve unsolvable problem instances. In the sampling based motion planning framework, it is assumed the availability of a collision detection function. Given a configuration, the collision checker determines whether a configuration belongs to \( C_{\text{free}} \) or to \( C_{\text{obs}} \). Formally, it is a function \( \text{Check} : C \to \{0,1\} \) (1) where 0 indicates the sample belongs to \( C_{\text{obs}} \), and 1 indicates the sample belongs to \( C_{\text{free}} \). In many practical situations robots are not allowed to execute arbitrary motions. A classical example is a car-like robot. In this case the robot is not permitted to perform certain actions, like for example to move along the axis connecting the rear wheels. These limitations are usually defined as differential constraints, i.e. equations or inequalities involving not only the degrees of freedom, but also their time derivatives. In the related literature the configuration space \( C \) is frequently substituted with the state space \( \mathcal{X} \), which includes both the degrees of freedom and their derivatives. An element of the state space is then in the form \((x,\dot{x})\), where \( \dot{x} \) indicates the first order time derivative. Differential constraints assume the form \( f(x,\dot{x}) = 0 \). If the constraints are not integrable the problem is called non holonomic motion planning. If the constraints depend on \( x \) and limit the possible values of \( \dot{x} \) and/or \( \ddot{x} \), the problem is called kinodynamic motion planning. For instance, a bound on the maximal speed (dynamic constraint) might be not absolute but rather related to the position (kinematic constraint) of the robot in its environment. This could allow higher speeds in wide areas and force slow motions when the robot is near to an obstacle. The exact solution of the three dimensional kinodynamic problem is NP-hard, while approximated dynamic programming based solutions have been illustrated in [24],[22] and [23].

## 3 Probabilistic Roadmaps

Probabilistic roadmaps (PRM), introduced in [37] (see also [34],[58] for preliminary versions). For sake of completeness it has to be acknowledged that some related ideas can be found in the earlier work [26]. It should also be mentioned that in the same period a similar approach was introduced in [56], the so called Ariadne’s clew algorithm. The difference is that the Ariadne’s clew algorithm does not explore the configuration space, but rather the trajectory space. The PRM algorithm works in two steps, the first called learning stage and the second called query stage. Given an instance of the RMP problem, in the learning stage the algorithm samples the configuration space and builds an undirected graph \( G = (V,E) \) which captures the information gathered. The graph is called probabilistic roadmap (PRM). In the query stage, the PRM

---

1even higher order derivatives could be included, for example to take into account accelerations and so on.
is used to solve specific RMP problem instances which are then reduced to a graph search. The availability of the following elements is assumed:

- a subroutine \textit{Check} which computes the function described in equation 1
- a subroutine \textit{Distance} which computes a distance between two configurations, i.e. it computes a function
  \[ D : \mathcal{C} \times \mathcal{C} \rightarrow \mathbb{R}^+ \cup \{0\} \] (2)
  that associates two configurations with a non-negative real number.
- a fast and possibly incomplete deterministic planner

3.1 The learning stage

The learning algorithm is illustrated in algorithm 1. Samples randomly generated over \( \mathcal{C} \) are accepted if they belong to \( \mathcal{C}_{\text{free}} \), and discarded otherwise. When a sample is accepted, it becomes a vertex of the PRM graph. After a vertex is added, the algorithm checks if it is possible to add edges between the inserted vertex and vertices already in the graph. For this aim a subset of neighboring vertices are selected and the deterministic planner is run to determine if the new vertex can be connected to them. Two vertices are neighbors if their distance \( D \) is less than a fixed threshold \( M \). This choice is made for sake of efficiency, as it is unlikely that a couple of far apart vertices could be connected by the simple planner. At the same time we wish to minimize the number of calls to the simple planner. Another often used efficiency driven choice is to limit the size of the neighbors set to a maximum size, say \( K \). If the planner succeeds in finding a free path between them, and if the nodes do not belong to the same connected component of the graph, an edge connecting the two vertices is added to the graph. Even if different techniques have been evaluated \([2],[25]\), in the vast majority of implementations the deterministic planner simply connects the two points with a straight segment and verifies if it lies in \( \mathcal{C}_{\text{free}} \) or not. This is done by selecting a set of intermediate points along the segment and by calling the collision checker on each of them. The segment is declared to be free if all the intermediate points lie in \( \mathcal{C}_{\text{free}} \). This approach is inherently error prone, as just a discretization is used to determine the validity of the entire segment. Recently however a new algorithm which computes exact collision checking has been introduced \([63]\), and its use appears appealing in the context of sampling based RMP algorithms, as it can be used to perform exact validation of the edges. If the resulting graph contains more than one connected component (see figure 1), the learning stage is often followed by a roadmap improving substep. The improving is done by selecting some vertices assumed to lie in difficult regions and then trying to add more samples in their neighborhood and more edges. Different heuristics can be used to decide if a vertex is in difficult region or not (see for example \([37]\)). If the configuration space is indeed disconnected, the improving step could even be not necessary, meaning that it could not improve the overall roadmap quality at all. On the other hand, due to the approximated nature, it is unfeasible to determine whether the improving step is indeed needed or not.

3.2 The query stage

In the query stage two configurations \( x_{\text{start}} \) and \( x_{\text{goal}} \) are given, and the algorithm is required to produce a path between them, provided it can be extracted from the graph (see algorithm 2). The algorithm tries to connect the two points to vertices in the graph \( G \). This trial is done by using the same technique used to insert edges in the roadmap, i.e. vertices are probed by increasing distance order. If it is not possible to connect both \( x_{\text{start}} \) and \( x_{\text{goal}} \) to the roadmap

\begin{algorithm}[h]
1: \( V \leftarrow \emptyset \)
2: \( E \leftarrow \emptyset \)
3: \textbf{loop}
4: \hspace{1em} Generate a random configuration \( c \in \mathcal{C}_{\text{free}} \)
5: \hspace{1em} \( V \leftarrow V \cup \{c\} \)
6: \hspace{1em} \( V_n \leftarrow \{v \in V \mid \text{Distance}(c, v) < M\} \)
7: \hspace{1em} \textbf{for all} vertices \( v \in V_n \) in order of increasing \( \text{Distance}(c, v) \) \textbf{do}
8: \hspace{2em} \textbf{if} \( c \) and \( v \) can be connected by the simple planner and they do not lie in the same connected component \textbf{then}
9: \hspace{3em} \( E \leftarrow E \cup \{(c, v)\} \)
\end{algorithm}

Figure 1. An example of Probabilistic Roadmap. Black regions indicate \( \mathcal{C}_{\text{obs}} \). In this case the PRM consists of two connected components and a roadmap improving stage could succeed in merging them.
the path connecting them with a straight line. Random couple of configurations and trying to replace useless motions. This is usually done by picking some random couple of configurations and trying to replace the path connecting them with a straight line.

Algorithm 2 Basic PRM algorithm: query stage

\[
\begin{align*}
V_s & \leftarrow \{ v \in V \mid \text{Distance}(x_{start}, v) < M \} \\
\text{if} \quad \text{the planner can find a path between } x_{goal} \text{ and a vertex in } V_s \quad \text{then} \\
\quad \text{Let } v_s \in V_s \text{ be that vertex} \\
\quad \text{return Failure} \\
V_g & \leftarrow \{ v \in V \mid \text{Distance}(x_{goal}, v) < M \} \\
\text{if} \quad \text{the planner can find a path between } x_{goal} \text{ and a vertex in } V_s \quad \text{then} \\
\quad \text{Let } v_g \in V_g \text{ be that vertex} \\
\quad \text{return Failure} \\
\text{if} \quad \text{a path } P \text{ between } v_s \text{ and } v_g \quad \text{is found} \quad \text{then} \\
\quad \text{return the overall solution path } \left( x_{start}, v_s \right), P_s \left( v_g, x_{goal} \right) \\
\text{else} \quad \text{return Failure}
\end{align*}
\]

3.3 Remarks on the PRM algorithm

The PRM algorithm has been successfully used to solve problems with many degrees of freedom. There is also experimental evidence that the algorithm fits well in a parallel computational environment [3]. However, some drawbacks were also outlined and motivated the need for further research. First, it is evident that the learning stage will take much more time than the query stage. Therefore, the learning stage is worth only if many queries will benefit from the created roadmap.

3.3.1 Extensions to the PRM algorithm

After the introduction of the aforementioned algorithm, there have been various extensions proposed, like lazy PRMs [10] or visibility-based probabilistic roadmaps [57]. In this subsection in particular we describe this last extension to the original PRM framework. One of the bottlenecks of PRMs is that as the number of samples grows, it becomes more and more expensive to updated the graph. It would then be beneficial to keep the graph’s size low. In the proposed algorithm, nodes in the graph belong to two different categories: guards and connection nodes. To each guard is associated a visibility region, i.e., the region of points in $C_{free}$ that can be reached with a straight line segment. Connection nodes are nodes placed in the intersections of the regions associated with two different guards. Edges are created only between nodes of different types, i.e., between guards and connection nodes. This way, nodes are added to the roadmap only when they really improve it, i.e., when they allow to create paths previously not possible. Nodes generated into the visibility region of a single guard are not added to the graph, as this would not create paths previously not possible. Experimental results outline that with the same amount of generated random samples, this technique allows to cover more or less the same portion of the configuration space. At the same time, because of the restricted number of nodes in the graph, the processing time turns out to be much smaller.

3.4 The problem of narrow passages

As already stated, most of the proposed PRM based approaches rely on uniform sampling over $C$. Uniform sampling poorly deals with narrow passages. In fact, if we indicate with $\mu(S)$ the measure of the set $S$, by using random sampling over $C$ the probability of placing a sample inside $S$ is $\mu(S)/\mu(C)$. This clearly indicates the inability of the algorithm to quickly find out small volume regions.

3.4.1 Obstacle based and medial axis probabilistic roadmaps

The problem of narrow passages is tackled in [1]. The authors address the problem in the context of Obstacle-Based Probabilistic Roadmaps (OBPRM from now on). OBPRM [4] are a variant of the PRM algorithm where node generation is performed with the goal of placing samples near to or in contact with the obstacles. The underlying idea is that in this way it is possible to correctly operate even in the presence of cluttered environments, as narrow passages are the result of facing obstacles. The authors illustrate then
# a set of different approaches both for node generation and for roadmap connection. Nodes generation is performed by using three different methods. The first one generates configurations in contact with obstacles (see algorithm 3). The second one is the usual straight line planner used in the simulation, while trying to connect it to an intermediate configuration along the line connecting two nodes. The last planner is an A∗-like planner. During roadmap connection, three different local planners are used. The first one is the so-called rotate-at-1, rotate-at-0, rotate-at-1, A∗. Thus, by following an increasing planning cost strategy, expensive local planners are used just when cheaper and simpler planners fail to succeed. The authors report extensive simulation results illustrating that significant speedups can be obtained by using the combination of techniques they propose and also provide experimental driven recommendations about the techniques to utilize. The use of many different sampling and connecting techniques however has its own drawbacks, as many parameters should be fixed and it can then be non-trivial to determine a suitable combined tuning. To overcome these difficulties, a slightly different approach that uses sampling on the medial axis of $C_{\text{free}}$ was proposed [53][66][67]. In this framework, called MAPRM, Medial Axis PRM, samples are not generated on the surface of the obstacles, but rather over $C$ and are then retracted into the medial axis of $C_{\text{free}}$. The medial axis of the configuration space are the points in $C_{\text{free}}$ with maximal distance from $C_{\text{obs}}$. Formally, for $x \in C_{\text{free}}$, we define $B_{C_{\text{free}}}$ to be the largest closed ball centered in $x$ and completely lying in $C_{\text{free}}$. The medial axis of the space of free configurations are defined as the set of points whose associated $B_{C_{\text{free}}}$ are maximal, i.e.: $MA(C_{\text{free}}) = \{ x \in C_{\text{free}} | \exists y \in C_{\text{free}} \}$ with $B_{C_{\text{free}}}(x) \subseteq B_{C_{\text{free}}}(y)$. Known properties of medial axis guarantee that the network or medial axis associated with the configuration space captures the connectivity of the space itself. Therefore, by relying on this reduced representation no significant information is lost. The strength of the algorithm relies on the ability to efficiently push or pull a sample to a medial axis. The authors report algorithms for dealing both with two and three dimensional workspaces, while here (see algorithm 4) we sketch the simple algorithm for retracting a sample into the medial axis of a two dimensional environment. Once a sample $c$ over $C$ is generated, the nearest point lying on the boundary of $C_{\text{free}}$ is determined (here it is indicated as $n$). Then, if $c$ lies in $C_{\text{free}}$, it is retracted to the medial axis, otherwise the point to move is $n$. The line to move along in order to reach the medial axis is determined by $c$ and $n$, while the direction depends whether $c$ is in $C_{\text{free}}$ or not. In order to efficiently perform the computation, the retraction step (line 9) is performed by using a bisection technique. The overall PRM algorithm generates samples uniformly over $C$.

## Algorithm 3

Algorithm for creating samples on the boundary of the obstacle $O_j$

1. GENERATE_CONFIGURATION
2. determine a point $p$ inside the obstacle $O_j$
3. let $M$ be a set of directions emanating from $p$
4. for all $m \in M$ do
5. use binary search to determine a point lying on the boundary of $O_j$ along the direction $m$

## Algorithm 4

Medial axis retraction algorithm

1: Let $c \in C$
2: Among the points in $\partial C_{\text{free}}$ determine the nearest to $c$, and call it $n$
3: if $c \in C_{\text{free}}$ then
4: $\vec{d} \leftarrow \vec{nc}$
5: $s \leftarrow c$
6: else
7: $\vec{d} \leftarrow \vec{ch}$
8: $s \leftarrow n$
9: Move $s$ along the direction $\vec{d}$. Stop moving $s$ when $n$ is not the unique nearest point of $\partial C_{\text{free}}$ to $s$
and the retracts them over the medial axis. A graph is then built by connecting those samples, and this builds up the probabilistic roadmap. The rational of this approach is the following: to discover narrow passages, it is no more necessary to generate samples into the narrow passages themselves, but rather to generate samples that once retracted end up into the medial axis associated with the narrow passages, thus increasing the probability of discovering them. This is achieved by sampling over the entire $C$ rather than over just $C_{\text{free}}$.

### 3.4.2 Planning in dilated spaces

Along the same lines of OBPRM, some authors [30] pushed the idea of sampling on obstacle surfaces even further, by allowing the generation of samples lying outside $C_{\text{free}}$. The planning is divided into two stages. First a roadmap is created in a dilated configuration space. This means that if a sample lies inside $C_{\text{obs}}$, but its distance from $C_{\text{free}}$ is smaller than a certain threshold $\delta$, it is retained rather than discarded. This is intuitive, as the uniform sampling process over the entire free configuration space, narrow passages are easier to detect, as they are widened. The choice of the value of $\delta$ is very important. Taking it too small would not give too many advantages over the basic PRM algorithm, but taking a too big value of $\delta$ has its disadvantages too, as entire obstacles could then disappear.

The authors illustrate the encouraging results of their approach is the following: to discover narrow passages, it is not necessary to generate samples into the narrow passages themselves, but rather to generate samples that once retracted end up into the medial axis associated with the narrow passages, thus increasing the probability of discovering them. This is achieved by sampling over the entire $C$ rather than over just $C_{\text{free}}$.

The authors found that by using a series of decreasingly dilated spaces better results can be obtained.

### 3.5 Probabilistic convergence of the PRM algorithm

The PRM algorithm is probabilistic complete, meaning that if enough time is alloted to the learn stage, it will eventually create a roadmap that will determine the solution of every solvable RMP problem instance. This is intuitive, as the uniform sampling process over $C_{\text{free}}$ will eventually cover it all, but from a practical point of view it would be precious to know how many nodes should be in the roadmap in order to get a desired probability of success. This is of course related to the shape of $C_{\text{free}}$, and to the placement of $x_{\text{start}}$ and $x_{\text{goal}}$. There are three parameters playing an important role in the overall planning performance. Let us suppose that there exists a path $p$ connecting $x_{\text{start}}$ and $x_{\text{goal}}$. The first relevant parameter is $L$, the length of $p$. The second parameter is $\varepsilon$ which is the Euclidean distance of $p$ from $C_{\text{obs}}$, and the third parameter is $N$, the number of vertices in the graph (i.e. $N = |V|$). The first result proved by the authors is the following.

**Theorem 3.1** Let $p : [0, L] \rightarrow C_{\text{free}}$ be a path connecting $x_{\text{start}}$ and $x_{\text{goal}}$ and let $\varepsilon$ be its distance from $C_{\text{obs}}$. Let $d$ be the dimension of the configuration space. Then the probability that the PRM will fail to connect $x_{\text{start}}$ and $x_{\text{goal}}$ is at most

$$\frac{2L}{\varepsilon}(1 - \alpha \omega_d)^N$$

where $\alpha = \varepsilon/(2^d |C_{\text{free}}|)$ and $\omega_d$ is the volume of the unit ball in the $d$-dimensional space.

The result provides two indications. First, the bound claims that the probability of failure decreases while increasing the number of samples in the roadmap. The second point is that the failure probability increases...
with the increase of path length. Again, this is somehow expected. Long paths require more information, i.e. more samples, to be caught. Also the dependence on \(\varepsilon\) is to be expected. It takes into account the problems given by narrow passages in \(C_{\text{free}}\), since more samples will be needed to discover them. Theorem 3.1 considers just the minimum distance between the path \(p\) and \(C_{\text{free}}\). The authors then provide a second bound which considers a mean distance between the path and the obstacle space.

**Theorem 3.2** Let \(p\) be a path of length \(L\) connecting \(x_{\text{start}}\) and \(x_{\text{goal}}\), i.e. \(p : [0,L] \rightarrow C_{\text{free}}\). Let \(\varepsilon(t)\) be the distance between the path and \(C_{\text{obs}}\) at instant \(t\). Then, the failure probability is bounded by

\[
6 \int_0^L \left(1 - \frac{\omega_d \varepsilon^{-d}(t)^N}{\varepsilon(t)}\right) dt \quad (4)
\]

where \(\alpha_d = 2^{-d} |C_{\text{free}}|\) and \(\omega_d\) is the volume of the unit ball in the \(d\)-dimensional space.

Both bounds depend either on \(\varepsilon\) or \(\varepsilon(t)\), and also on \(\alpha\). This bound is then far from being trivial to compute, since the exact computation of these parameters is not easy. They depend on the path \(p\) and on the shape of \(C_{\text{free}}\). A different analysis is presented in [6], [36], and [29]. It is performed assuming of the availability of a fast but incomplete planner, indicated as \(B_S\), and of a complex but complete planner, indicated as \(B_C\). In the following, two configurations are said to be visible if they can be connected by using the simple planner \(B_S\). Two basic concepts there introduced are the notion of \(\varepsilon\)-goodness and of adequate samples set.

**Definition 3.3** Let \(c \in C_{\text{free}}\) and let \(S(c) \subseteq C_{\text{free}}\) be the set of points visible from \(c\). Let \(\varepsilon > 0\) be a real number. A configuration \(c \in C_{\text{free}}\) is \(\varepsilon\)-good if \(\mu(S(c)) \geq \varepsilon \mu(C_{\text{free}})\), where \(\mu\) indicates the volume of the given set. \(C_{\text{free}}\) is \(\varepsilon\)-good if all its elements are \(\varepsilon\)-good.

**Definition 3.4** Let \(C_{\text{free}}\) be an \(\varepsilon\)-good space of free configurations. A set of samples \(V\) is adequate if the volume of \(C_{\text{free}}\) not reachable from \(V\) by using \(B_S\) is at most \((\varepsilon/2)\mu(C_{\text{free}})\).

The \(\varepsilon\)-goodness property states that from every point of \(C_{\text{free}}\) it is possible to see a significant portion of \(C_{\text{free}}\) itself, while a set of vertices is declared to be adequate if from that set the part of \(C_{\text{free}}\) not visible from it is bounded. Thus one can expect that an \(\varepsilon\)-good configuration space can be well covered by using not too many samples. The bounds on the failure probability are formulated in terms of the following preprocessing procedure, which is a slight variation of the basic PRM algorithm.

1. Generate \(k\) samples in \(C_{\text{free}}\)
2. Run the simple planner \(B_S\) over every couple of samples
3. Pick a sample from every connected component of the graph built so far
4. Use the complex planner \(B_C\) to try to connect couples of samples belonging to different components

The reader is referred to the cited papers for details on the fourth step, called permeation.

**Theorem 3.5** Let \(\beta \in [0,1)\) and let \(k = (c/\varepsilon)(\ln 1/\varepsilon + \ln 4/\beta)\) where \(c\) is a fixed positive constant large enough that for all \(x \in [0,1)\) the inequality \((1-x)^{(c/\varepsilon)}(\ln 1/\varepsilon + 4/\beta) \leq x/4\) holds. In such hypothesis the preprocessing stage will generate an adequate samples set with probability at least \(1 - \beta\).

An additional bound can be obtained for the query step, provided that the the it is performed according to the algorithm illustrated in algorithm 6. In that case the following theorem holds.

**Theorem 3.6** If the samples set produced by the preprocessing stage is adequate, then the probability that the query algorithm outputs FAILURE is at most \(\gamma\).

A different type of analysis is presented in [41], where a framework based on probability spaces is introduced. From the two theoretical analysis briefly summarized, it is evident that while to a certain extent it is feasible to prove the probabilistic convergence of the PRM based algorithms, it is far from trivial to provide the numbers for a given environment. It is then still not possible to derive expectations on the required number of samples needed to achieve a given success probability while solving a generic RMP problem instance.
4 Tree based randomized motion planners

Samples and edges can also be organized in a tree rather than in a graph. By using this approach efficient planners have been designed. They are well suited for addressing single-shot motion planning problems, and while growing a tree it is possible to utilize the motion equations of the robot, thus obtaining paths complying with kinodynamic constraints.

4.1 Rapidly Exploring Random Trees

Rapidly Exploring Random Trees (RRT) are a class of RMP algorithms that can be used both for systems involving kinodynamic constraints or not [39],[50],[19],[40],[51],[52],[45]. RRT proved to be suitable for being used in very different real world applications [39],[11]. In addition to the Check and Distance routines used in the PRM framework, the RRT algorithm assumes the availability of the following elements:

- a set $U$ of inputs to be applied to the system
- an incremental simulator, i.e. a procedure that given a state $x(t) \in \mathcal{X}$ and an input $u \in U$, produces the state $x(t+\Delta t)$, provided that the input $u$ has been applied over the given time interval.

Then, by including system’s equations into the incremental simulator, the planner is able to directly produce paths satisfying the kinodynamic constraints. If no such constraints are given, i.e. the planner is required to produce a path for a holonomic robot, no incremental simulation takes place and simple interpolation is performed, as every motion is allowed. The basic version of the algorithm is given in 7. The algorithm starts by building a tree rooted at the starting point $x_{\text{start}}$. Samples are then randomly generated over $C_{\text{free}}$. If the incremental simulator is included, the NEW.STATE subroutine (called in line 3 of the EXTEND substep) chooses an input $u$, either randomly or by determining the one which will give a new state as closed as possible to the new random state, and determines a new state to be added to the tree. The routine returns Reached if the new sample can be reached, Advanced if it cannot be reached but a new state has been added, or Trapped if no new state has been produced. If the simulator is not needed, NEW.STATE simply tries to place the new state at a fixed distance from $x_{\text{near}}$ along the segment connecting it with $x$ (see figure 2). The rationale behind the RRT algorithm is the following (see figure 3). Let $x$ be a node in the tree $T$ and let $V(x)$ be its associated Voronoi region, i.e. the set of states nearer to $x$ than to every other state in $T$. Then, by uniformly sampling over the state space, it is more likely to place samples into a big Voronoi region rather than into a small one. If a sample is placed into $V(x)$, then $x$

Algorithm 7 Algorithms for the construction of an RRT

1: BUILD_RRT($x_{\text{init}}$)
2: $T$.init($x_{\text{init}}$)
3: for $k = 1$ to $K$ do
4:     $x_{\text{rand}} \leftarrow$ NEAREST_NEIGHBOR($x, T$)
5:     EXTEND($T, x_{\text{rand}}$)
6: return $T$
7: EXTEND($T, x$)
8: $x_{\text{near}} \leftarrow$ NEAREST_NEIGHBOR($x, T$)
9: if NEW_STATE($x, x_{\text{near}}, x_{\text{new}}, u_{\text{new}}$) then
10:     $T$.add_vertex($x_{\text{new}}$)
11:     $T$.add_edge($x_{\text{near}}, x_{\text{new}}, u_{\text{new}}$)
12: if $x_{\text{new}} = x$ then
13:     return Reached
14: else
15:     return Advanced
16: return Trapped

Figure 2. Extension of an RRT. Starting from a randomly sample $x_{\text{rand}}$ generated over the state space $X$, the nearest RRT node is found ($x_{\text{near}}$), and a new node is created as its child. The new node is placed along the segment connecting $x_{\text{near}}$ and $x_{\text{rand}}$ if the system is holonomic, otherwise it is generated by applying the incremental simulator to $x_{\text{near}}$

Figure 3. A RRT built over an obstacle free $[0,1]^2$ state space and the associated Voronoi regions
will be chosen to be extended. Thus the tree is biased to grow towards unexplored regions. The schema depicted in figure 7 simply builds a RRT which explores the state space starting from the given \( x_{\text{start}} \) point. If a couple of points is given in a single shot framework, a significant speedup is obtained by growing two trees, one from \( x_{\text{start}} \) and the other from \( x_{\text{goal}} \). The RRT-Connect algorithm [40], designed for problems not involving kinodynamic constraints, exploits this technique, as well as a greedy tree extension to cut down planning time even more. Figure 8 illustrates this improved version. An ever more aggressive behavior can be obtained by using always the CONNECT routine instead of alternating it with EXTEND. This version of the planner is often indicated as RRT-ConCon. In this way, as soon as a promising direction is discovered, the tree is expanded in that direction as much as it is possible thus decreasing exploration time.

**Algorithm 8** The RRT-Connect algorithm

```plaintext
1: CONNECT(\( T, q \))
2: repeat
3: \( S \leftarrow \) EXTEND(\( T, x_{\text{rand}} \))
4: until \( S = \text{Advanced} \)
5: return \( S \)
```

**Theorem 4.1** Let \( x_{\text{init}} \) and \( x_{\text{goal}} \) lie in the same connected component of a nonconvex, bounded, open, \( n \)-dimensional connected component of an \( n \)-dimensional state space. The probability that an RRT constructed from \( x_{\text{init}} \) will find a path to \( x_{\text{goal}} \) approaches one as the number of RRT vertices approaches infinity.

A similar theorem holds for nonholonomic systems. In what follows it is assumed that in the NEW_STATE routine the input \( u \) is uniformly randomly chosen over the set of available inputs \( U \).

**Theorem 4.2** In the same hypothesis of theorem 4.1, let further assume that \(|U|\) is finite, \( \Delta t \) is constant, and no two RRT vertices lie within a specified \( \varepsilon > 0 \), according to the used metric Distance. Let also assume that there exists a sequence \( u_1, \ldots, u_m \) of inputs that when applied to \( x_{\text{init}} \) will lead the system to the state \( x_{\text{goal}} \). Then the probability that an RRT initialized at \( x_{\text{start}} \) will contain a vertex in the \( X_{\text{goal}} \) region approaches 1 as the number of vertices approaches infinity.

While valuable in itself, probabilistic convergence only ensures convergence to the solution when the number of vertices, and then the computation time, approaches infinity. As with PRM, it would be highly useful to have a rate of convergence of the planner, in order to be able to predict the expected time. Again, while some results have been obtained, they are expressed in terms of environment specific quantities not easy to determine. The following theorems apply to single RRT and assume that an instance of the RMP problem is given in terms of a starting point \( x_{\text{goal}} \) and of a goal region \( X_{\text{goal}} \), i.e. the robot is required to reach a region rather than a point. Both theorems rely on the following definition.

**Definition 4.3** A sequence of subsets \( \mathcal{A} = \{A_1, A_2, \ldots, A_k\} \) of the state space \( X \) is an attraction sequence if \( A_0 = \{x_{\text{init}}\} \), \( A_k = X_{\text{goal}} \), and for each \( A_i \) there exists a basin \( B_i \subseteq X \) such that:

1. for all \( x \in A_{i-1} \), \( y \in A_i \), and \( z \in X \setminus B \), the metric Distance yields \( \text{Distance}(x, y) < \text{Distance}(x, z) \)
2. for all \( x \in B_i \), there exists a number \( m \) such that the sequence of inputs \( \{u_1, u_2, \ldots, u_m\} \) selected by the EXTEND algorithm will bring the state into \( A_i \subseteq B_i \)

Given a set \( S \), we indicate with \( \mu(S) \) its measure.

**Theorem 4.4** Let assume that a connection sequence \( \mathcal{A} = \{A_1, A_2, \ldots, A_k\} \) of length \( k \) exists, and let \( p = \min_i \{\mu(A_i)/\mu(X_{\text{free}})\} \). Then, the expected number of iterations required to connect \( x_{\text{start}} \) and \( X_{\text{goal}} \) is no more than \( k/p \).

**Theorem 4.5** If an attraction sequence of length \( k \) exists and \( \delta \in (0,1] \), then the probability that the RRT finds a path after \( n \) iterations is at least \( 1 - \exp(-np\delta^2/2) \), where \( \delta = 1 - k/(np) \), and \( p \) is defined as in theorem 4.4.

Both theorems 4.4 and 4.5 suffer from the dependence on \( k \), the length of the attraction sequence. While given a solvable instance of the RMP problem one can assume the existence of such sequence, the number of elements in it depends heavily on the shape of the environment and is far from being easy to compute.
4.1.2 Remarks on the RRT algorithm

The EXTEND substep of the RRT algorithm starts by determining the nearest node to the last generated sample. This has at least two implications from a practical point of view. First, the search has to be performed over the whole set of nodes generated so far. If one does not adopt a suitable data structure, but rather scans the whole sequence, this will yield a quadratic dependence. This problem has been addressed in [5], where the problem of efficient neighbor search is tackled and a solution based on $Kd$-trees is proposed, yielding an overall $n \log n$ complexity. It has however to be pointed out that the techniques utilized are quite involved, and could take some effort to be implemented. While implementing this technique, one has additionally to take care that the topology of $C$ is respected. The second important issue related to neighbor search is the metric used. The choice of a good metric is a fundamental problem, as the use of an inappropriate one could lead the tree to grow toward the wrong direction. Ideally, the value returned by the Distance function should reflect the cost to go, while moving from one state to another. It is evident that this cost depends on the underlying system model and that the metric should then be strictly related to it. This problem is well discussed in [18]. Recently, some possible extensions for the RRT algorithm were introduced. In [64], the idea of bidirectional search is pushed forward, towards multiple trees based search. These additional trees, called local trees, are generated when a newly generated sample lies in free space, but cannot be connected to any of the already created trees. An upper bound on the number of trees is considered as well in order to eliminate the possibility to create too many trees. Experiments show that this expedient can significantly reduce the time needed to solve motion planning problems in maze like environments with narrow passages. A similar idea has also been proposed in [59], where nodes in the PRM roadmaps are substituted with trees. The authors also address how this schema can be efficiently implemented over distributed architectures in order to exploit the inherent parallelism.

4.2 Planning in expansive spaces

An approach similar to RRT have been proposed in [32], [38] [28] and [31]. As the RRT planner, this planner efficiently builds a tree data structure. We first illustrate the basic version which does not deal with kinodynamic constraints. Given an instance of the motion planning problem, the algorithm starts building two trees, one rooted at the start point $x_{\text{start}}$, and the other rooted at the goal point $x_{\text{goal}}$. As for the PRM algorithm, we assume that a tree $T$ consists of a couple of sets $T = (V, E)$, where $V$ is the set of tree nodes and $E$ is the set of edges between nodes. The two trees are iteratively expanded by using the same algorithm, and the process terminates if it is possible to find a free path connecting the two trees. Algorithm 9 illustrates this iterative approach. The iteration terminates when either a solution is found or the maximum number if iterations is reached. Algorithm 10 illustrates how a tree $T = (V, E)$ can be expanded. In what follows, let $B_d(s)$ be the ball of radius $d$ centered in $s$. At each step the algorithm associates a weight with every node in $V$. The weight of the node $s \in V$ is the number of sampled nodes of $V$ lying in $B_d(s)$, i.e.

$$w(x) = |V \cap B_d(s)|.$$  

The goal of the weight function is to avoid oversampling in regions already explored and to rather bias the expansion towards unexplored areas of the configuration space. In this respect both RRT and the expansive planner aim to the same goal, the only difference being in the technique used to identified poorly explored zones. Finally, algorithm 11 illustrates how a connection between trees is verified. To limit the number of useless trials, the algorithm ignores nodes couples too far apart. The algorithm assumes that a path can be found if a couple of nodes is close enough. In that case the segment is stored so that it can be later used to produce the path connecting $x_{\text{start}}$ with $x_{\text{goal}}$. The above algorithm can be adapted in order to deal with kinodynamic constraints. In this case, a single
Algorithm 11 Connection
1: CONNECT$(T_1, T_2)$
2: for all $x \in V_1$ do
3: for all $y \in V_2$ do
4: if Distance$(x, y) < \text{Threshold}$ then
5: if $(x, y) \in C_{\text{free}}$ then
6: store $(x, y)$
7: return TRUE
8: return FALSE

The tree is built, but the samples space is not $X$ but rather $CT = C_{\text{free}} \times [0, +\infty]$ which is called \textit{space$\times$time}. The subset of free valid configurations of $CT$ is indicated as $CT_{\text{free}}$. Along the same lines of the RRT algorithm, it is assumed the availability of an incremental simulator and of a set of inputs $U_l$. In this context it is assumed that inputs in $U_l$ are piecewise constant functions with at most $l$ pieces. Algorithm 12 illustrates how it is possible to generate a trajectory complying with the kinodynamic constraints. A problem instance is again formulated in terms of a start point and of a goal region, which the authors indicate call \textit{ENDGAME} and will be here indicated as $E$. Extensive results over simulations and real robots are illustrated in [31]. The trials involved both nonholonomic robots and systems performing in dynamic environments, i.e., with moving obstacles. Detailed results provide evidence that the devised algorithms lead to real time compliant systems.

4.2.1 Probabilistic convergence

The former algorithms have been formulated in a framework based on the \textit{expansiveness} concept introduced in [32]. We here report the generalized results illustrated in [31] which concerns the kinodynamic motion planner. Given $(s, t)$ and $(s', t') \in CT_{\text{free}}$ we say that $(s', t')$ is reachable from $(s, t)$ if there exists a control function that leads to an admissible trajectory from $(s, t)$ to $(s', t')$. If such a trajectory can be obtained by applying just the inputs of the $U_l$ set, then we say that $(s', t')$ is $l$-reachable from $(s, t)$. According to these definitions, it is possible to define the set of points reachable and $l$-reachable from a point $p = (s, t)$. We indicate the first set as $R(p)$ and the second as $R_l(p)$. Then, given a subset of $S \subset CT_{\text{free}}$, it is possible to define its reachable sets:

$$R(S) = \bigcup_{p \in S} R(p)$$

$$R_l(S) = \bigcup_{p \in S} R_l(p)$$

Definition 4.6 Let $\beta \in [0, 1)$ be a constant and Let $S \subset CT$. The look out of the set $S$ is

$$\text{Lookout}_\beta(S) = \{ p \in S | \mu(R_l(p)) \setminus S \geq \beta \mu(R(S) \setminus S) \}$$

Definition 4.7 Let $\alpha, \beta$ be constants in $[0, 1]$. For any $p \in CT_{\text{free}}$, $R(p)$ is $(\alpha, \beta)$-expansive if for every connected subset $S \subseteq R(p)$,

$$\mu(\text{Lookout}_\beta(S)) \geq \alpha \mu(S).$$

$CT_{\text{free}}$ is $(\alpha, \beta)$-expansive if for every $p \in CT_{\text{free}}$, $R(p)$ is $(\alpha, \beta)$-expansive.

The following theorem proves that the algorithm will reach the \textit{ENDGAME} region, i.e., will succeed in finding a solution, with high probability.

Theorem 4.8 Let $X$ be the reachability of the start point $(s, t)$ and let $g = \mu(E \cap X)$ be strictly positive. Let $X$ be $(\alpha, \beta)$-expansive. Let $\gamma \in [0, 1]$ be a constant. Let $T$ be a tree rooted at $(s, t)$ with $r$ nodes. The probability that $T$ has a node in $E$ is at least $1 - \gamma$ if

$$r \geq k \alpha \frac{2k}{\gamma} + \frac{2}{g} \ln \frac{2}{\gamma},$$

where $k = (1/\beta) \ln(2/g)$.

A set of similar results and definitions holds for the basic planner that does not deal with kinodynamic constraints. It is again evident that probabilistic convergence can be proved, but convergence rate is difficult to measure in terms of the problem instance to be solved.

5 Practical considerations

Given a motion planning problem, the choice of the planning algorithm to use is driven by different factors. The first aspect to consider is whether the problem involves kinodynamic constraints or not. If this is the case, the choice is for one of the the two algorithms illustrated in section 4. Up to now analytic comparison is available, and also no fair experimental comparisons have been performed. On the other
hand both algorithms proved to be suitable for being used in real world applications, they address the same class of problems, and they require the same components. Certain authors report that expansive planners are more difficult to tune because of the higher number of parameters. It is however somehow difficult to give general indications on the one which could better fit the needs, or could be easier to implement. If the problem to be solved involves just kinematic constraints, then all the proposed algorithms can be used. In the single shot scenario, tree based algorithms are in general much faster. It has however to be pointed out that speed comes to the price of path quality, since these planners stop as soon as a path is found. PRM based planners, instead, can produce a set of paths, and then the most favorable one is returned. In a situation where many successive queries have to be solved, also the use of the basic PRM algorithm appears appropriate. If the operating environment exhibits a configuration space with narrow passages, then one of the outlined refined PRM algorithms is the choice. It is nevertheless evident that in general no algorithm is better, but rather the environment influences the performance. The opportunity of having more planners to be used in different regions is addressed in [21], but up to now no well defined heuristic is available to drive the choice.

Another important issue is the sampling and resampling strategy. The vast majority of the proposed planners propose uniform sampling over either $C$ or a suitable subset. This leads to easy implementation, but has the outlined drawbacks. For what concerns resampling, associating a weight to each vertex and then choosing vertices to resample with a probability proportional to the inverse of the weight is easy to implement. The easiest weight to compute is the number of edges outgoing from a vertex. Also the weight suggested in algorithm 10 is easy to compute, but could take more time.

Collision detection is a challenging problem in itself, but fortunately there exist very efficient algorithms whose implementations are freely available to the scientific community. These algorithms often assume that the description of the objects is given in terms of meshes of triangles. This is a very favorable hypothesis, as many CAD systems export this type of representation for solid objects. However different algorithms exhibit different performances in various operating scenarios and a preliminary evaluation is needed in order to select the one better fitting the needs of the problem to be solved. The choice of the collision detector is extremely important, as most of the time spent by planners is devoted to collision checking, both for validating samples and edges connecting samples. Another important practical aspect concerns the Distance function. Since this is much easier to implement, it is practical to try different definitions and than rely on the one giving better experimental results. This is extremely important since sampling based algorithms use the Distance function in order to decide how the supporting data structure will be expanded. Common choices are the $L_1$, $L_2$ or $L_\infty$ norms in the configuration space $C$. While computing distances between configurations, it is also usual to assign different weights to the degrees of freedom, or to normalize them to a given common interval. This is usually the case when both translational and rotational joints are present, as rotating and translating can have a different impact on the geometry of the system.

6 Conclusions

We presented the most influential algorithms developed in the last years in the field of randomized robot motion planning. This paper illustrated the most common sampling based algorithmic techniques, namely graph based and tree based. The field is however continuously growing, and more and more refinements are being proposed, so that an exhaustive enumeration of the many possible variations is doomed to early obsolescence. The user who needs to implement them should have had concrete indications about their strength and limitations, and will not find too difficulties in adapting them to its specific needs.
