Do Crosscutting Concerns Cause Defects?

Marc Eaddy, Student Member, IEEE, Thomas Zimmermann, Member, IEEE, Kaitlin D. Sherwood, Vibhav Garg, Gail C. Murphy, Member, IEEE Computer Society, Nachiappan Nagappan, Member, IEEE, and Alfred V. Aho, Fellow, IEEE

Abstract—There is a growing consensus that crosscutting concerns harm code quality. An example of a crosscutting concern is a functional requirement whose implementation is distributed across multiple software modules. We asked the question, “How much do the concerns of a program affect the number of defects in a program?” We conducted three extensive case studies to help answer this question. All three studies revealed a moderate to strong statistically significant correlation between the degree of scattering and the number of defects. This paper describes the experimental framework we developed to conduct the studies, the metrics we adopted and developed to measure the degree of scattering, the studies we performed, the efforts we undertook to remove experimental and other biases, and the results we obtained. In the process, we have formulated a theory that explains why increased scattering might lead to increased defects.

Index Terms—Crosscutting concerns, fault proneness, feature location, requirements traceability, mining software repositories, metrics, statistical analysis, empirical software engineering, open source software.

1 INTRODUCTION

D espite the significant effort that developers put into producing reliable software, defects still surface after the software is deployed. Defects creep in at every stage of the development process, avoid detection during testing, and all too often appear as failures to the end user. Enormous effort goes into avoiding defects (e.g., defensive programming), and when that fails, detecting defects (e.g., code inspections, program analysis, prerelease testing) to reduce the number of defects in a delivered software system. These efforts might be better directed if we had a better understanding of what causes defects.

This paper considers the possibility that one cause of defects is poor modularization of the concerns of the program. A concern is any consideration that can impact the implementation of a program [53]. A software requirement is an example of a kind of concern. When a concern’s implementation is not modularized, that is, the implementation is scattered across the program and possibly tangled with the source code related to other concerns, the concern is said to be crosscutting [42]. Several empirical studies [25] [28] [29] [30] [47] [60] [64] provide evidence that crosscutting concerns degrade code quality because they negatively impact internal quality metrics (i.e., measures derived from the program itself [41]), such as program size, coupling, and separation of concerns.

But do these negative impacts on internal quality metrics also result in negative impacts on external quality? Internal metrics are of little value unless there is convincing evidence that they are related to important externally visible quality attributes [35] [38], such as maintenance effort, field reliability, and observed defects [21].

We argue in this paper that crosscutting concerns1 might negatively impact at least one external quality attribute—defects, i.e., mistakes in the program text. Our theory is that a crosscutting concern is harder to implement and change consistently because multiple—possibly unrelated—locations in the code have to be found and updated simultaneously. Furthermore, crosscutting concerns may be harder to understand because developers must reason about code that is distributed across the program and must mentally untangle the code from the code related to other concerns. We hypothesize that this increased complexity leads to increased defects.

To formulate our theory, we present a formal model of concerns and their relationship to program elements, and we introduce a set of metrics that measure the extent to which that relationship is crosscutting. To test our hypothesis, we conducted three case studies to gather data on scattering and defect counts. We then applied correlation analysis to gather empirical evidence of a cause–effect relationship between scattering and defects.

We found a moderate to strong correlation between scattering and defects for all three case studies. This suggests that scattering may cause or contribute to defects,
which—if true—has many implications. First and foremost, our evidence suggests that one way we can improve software reliability is to modularize crosscutting concerns—or at least ensure they are well tested. Secondly, our findings suggest that cognitive complexity measures (e.g., concern-oriented metrics) are perhaps more appropriate predictors of software quality than structural complexity measures (e.g., coupling, code churn). Thirdly, it prompts the need for independent replication of our results to build confidence that the relationship between scattering and defects is real. Finally, our findings call for additional research to determine the root cause of the supposed relationship: Are changes to highly crosscutting concerns more likely to be applied inconsistently? Are crosscutting concerns inherently more difficult to understand?

The paper proceeds as follows. In Section 2, we present a theory of the relationship between crosscutting and defects, and state our research hypothesis. In Section 3, we describe our model of concerns and our suite of concern metrics that are based on the model. In Section 4, we outline the methodology we used to validate our theory. In Section 5, we describe our case studies. We present the results of our studies and a discussion in Section 6. We address threats to internal and external validity in Sections 7 and 8. We summarize related research in Section 9. Section 10 concludes.

2 WHY MIGHT CROSSCUTTING CONCERNS CAUSE DEFECTS?

Our theory is a set of models [31] that formalizes concepts such as “concerns,” “program elements,” and “defects,” and describes their inter-relationships, along with how they relate to the developer. In this section, we model the relationship between developers and concerns. We use the model to justify why crosscutting might cause defects, which we need to draw meaningful conclusions from our results [21].

Every line of code exists to satisfy some concern. Concerns may be described in many ways and at various levels of abstraction:

- Features from a feature list.
- Requirements from a software requirements document.
- Design patterns and design elements from a UML design document.
- Low-level programming concerns such as programming language used, coding style, programming idioms, code reuse, information hiding, and algorithms.

When faced with the task of implementing a concern, a developer creates—perhaps without realizing it—a concern implementation plan that guides her implementation decisions. It is in this plan that crosscutting first emerges. One developer’s plan may entail scattering the implementation (e.g., she plans to copy-and-paste code), whereas another may localize it (e.g., she plans to create a shared function). The plan chosen depends on many variables, including the development process (e.g., priorities, time, resources), programming technology (e.g., program language), and the developer’s aptitude.

The relationship between the concerns and the program is rarely documented [44]. This makes it difficult for maintainers of the program to answer questions such as “Where are all the places that the undo feature is implemented?” (i.e., top-down analysis [48]) and “What is this piece of code for?” (i.e., bottom-up analysis [48]). Without a proper understanding of the scattered nature of the concern implementation, maintainers may make changes incorrectly, or neglect to make changes in all the right places.

Our conjecture is that when the implementation of a concern is distributed (scattered) across many program elements, the complexity of that implementation increases, as does the difficulty of making changes correctly and consistently, increasing the likelihood of defects. Stated simply, crosscutting concerns are hard to find, understand, and work with. More formally, our research hypothesis is

Hypothesis. The more scattered a concern’s implementation is, the more defects it will have, regardless of the implementation size.

The last stipulation about size is necessary since past research has established that size, in terms of lines of code, is already a strong predictor of defects [22]. Since we expect scattering to be related to size, we must rule out the possibility that an increase in defects is caused by an increase in size alone. We will revisit this technicality in Section 6.3—so for now we ask the reader to ignore it.

Some controlled experiments on program understanding suggest our theory is valid. Letovsky and Soloway use the term delocalized plan to refer to a concern whose implementation is “realized by lines scattered in different parts of the program.” They observed that programmers had difficulty understanding delocalized plans, resulting in several kinds of incorrect modifications [46]. Similarly, Robillard, Coelho, and Murphy observed that programmers made incorrect modifications when they failed to account for the scattered nature of the concern they were modifying:

“Unsuccessful subjects made all of their code modifications in one place even if they should have been scattered to better align with the existing design.” [54]

Other studies indicate that programmers make mistakes when modifying classes whose implementations are scattered due to inheritance. Harrison, Counsell, and Nithi found that “systems without inheritance are easier to modify than systems with either three or five levels of inheritance.” [32]. From the perspective of our theory, inheritance scatters the implementations of the underlying concerns.

In another study, Bruntink, Deursen, and Touwé observed that the idiom used to implement a specific crosscutting concern (exception handling) made it “too easy to make small mistakes [that] can lead to many faults spread all over the system.” [9]

Finally, enhancements or fixes applied to a crosscutting concern may induce changes in multiple source files,
leading to increased code churn. Nagappan and Ball showed that code churn is a good predictor of system defect density [49], and we propose that changes to crosscutting concerns may be the root cause.

To validate our theory empirically and test our hypothesis, we next describe our concern model and a suite of metrics that operationalize the concept of “highly scattered.”

3 A MODEL OF CONCERNS

Abstractly, a program specification, or simply specification, is a description of a program. A specification may be executable, e.g., a set of program elements, or nonexecutable, e.g., a requirements specification or architectural design. Our operational definition of a concern is an item from a program’s nonexecutable specification. Thus, a nonexecutable specification represents a concern domain of the program.

We define our concern–program element mapping as a tuple $M = (S, T, C, c, R)$. $S$ is a set of concerns organized into a hierarchy [59] described by $C_s = \{ (s_i, s) \mid s_i, s \in S, s_i \neq s, s_i \text{ is the parent of } s \}$. $T$ is a set of program elements organized according to $C_t = \{ (t_i, t) \mid t_i, t \in T, t_i \neq t, t \text{ is the parent of } t \}$ in the abstract syntax tree [1] of the program. Finally, $R$ is the relation of interest between the two specifications, $R = \{ (s, t) \mid s \in S, t \in T \}$. This is depicted in Figure 1 below.

![Fig. 1. Relation between concerns and program elements.](image)

Note that $C_t$ does not describe a class inheritance hierarchy. It describes a forest of trees, the roots of which are the abstract syntax trees of the individual source files, which syntactically contain class definitions, which in turn contain class member definitions, etc.

The program elements that are meaningful depend upon the language in which the program is expressed. The projects analyzed in this paper were written in Java, so we are primarily interested in classes, fields, methods, and statements.

3.1 Terminology

We can now define some common terminology. A concern is scattered if it is related to multiple target elements and tangled if both it and at least one other concern are related to the same target element [5] [17] [24]. For the purposes of this paper, a crosscutting concern is a concern that is scattered [26, p. 4].

This binary definition of scattering is simple and unambiguous, but is not very useful when most of the concerns are scattered, which we believe to be the rule rather than the exception [17] [62]. Hence, we need metrics to determine the degree of scattering.

3.2 Concern Metrics

There are many ways to describe how a concern is implemented. For the purpose of validating our theory, we focused on four cognitive complexity metrics that describe how scattered the concern’s implementation is, in absolute terms and in terms of statistical distribution, and with respect to classes and methods (the elements of interest in an object-oriented implementation). This allows us to determine which characteristic of scattering, if any, is the best predictor of defects.

Complexity metrics tend to be heavily influenced by size (in terms of lines of code), which can lead a researcher to perceive a cause–effect relationship where none exists [22]. To test for a possible influence, we also measured the concern’s size, i.e., the total number of lines of code associated with the concern. We discuss the results of the concern size tests in Section 6.3.

Table 1 provides a summary of the metrics, which we will now describe in detail.

3.2.1 Program Element Contribution

Program element contribution (CONT) is the number of lines of code in a program element that are associated with a concern. The entire line is counted even if only a portion is associated with the concern. Indeed, a line may be associated with multiple concerns.
For a method or field associated with a concern, the contribution is the number of lines in the method (method declaration plus method body) or field declaration.

For classes, the contribution includes the lines of the class declaration plus the contributions of the class's methods and fields. Inner classes in Java are considered separate from the enclosing class when determining contribution, and anonymous classes are considered part of the enclosing method. Note that inheritance has no bearing on contribution.

When the element is the entire program, \( P \), the contribution is the sum of the contributions of all the classes, i.e., the total number of lines associated with the concern \( s \). We give this special case its own metric, lines of concern code (LOCC), that is, \( \text{LOCC}(s) = \text{CONT}(s, P) \).

### 3.2.2 Scattering Metrics

The concern diffusion metrics, created by Garcia and colleagues, measure scattering in absolute terms as a count of the number of classes (CDC) or methods (CDO) that implement the concern [25]. We include CDC and CDO in our correlation analysis because they are rigorously defined, are validated by several studies [25] [28] [30], and they nicely contrast our degree of scattering metric.

The degree of scattering metric (DOS) created by Eaddy, Aho, and Murphy [17] provides more information by further considering how the concern's code is distributed among the elements. We believe this more accurately quantifies the modularity of a concern, and so should be a better predictor of defects than absolute scattering metrics such as CDC and CDO. The degree of scattering metric builds upon the concentration metric (CONC) introduced by Wong et al. [62].

\[
\text{CONC}(s, t) = \frac{\text{Source lines in element } t \text{ related to concern } s}{\text{Source lines related to concern } s}
\]

For the object-oriented programs we studied, we measured degree of scattering across classes (DOSC), in which case \( t \) is a class, and degree of scattering across methods (DOSM), in which case \( t \) is a method.

Degree of scattering is a measure of the statistical variance [37, p. 57] of the concentration of a concern over all program elements with respect to the worst case (i.e., when the concern is equally scattered across all elements):

\[
\text{DOS}(s) = 1 - \frac{\text{Variance}(s)}{\text{Variance}_{\text{ideal}}(s)}
\]  

where,

\[
\text{Variance}(s) = \frac{\sum_{t \in T} (\text{CONC}(s, t) - \text{CONC}_{\text{worst}})^2}{|T|}
\]

The worst-case occurs when the implementation of a concern is uniformly distributed across all program elements in \( T \), i.e., \( \text{CONC}_{\text{worst}} = 1/|T| \). Substituting this into (4),

\[
\text{Variance}(s) = \frac{\sum_{t \in T} (\text{CONC}(s, t) - 1)^2}{|T|}
\]

The ideal variance occurs when \( \text{CONC} \) is 1 for one component \( t \), and 0 for all other components, i.e., the concern \( s \) is completely localized in \( t \). (5) reduces to

\[
\text{Variance}_{\text{ideal}}(s) = \frac{|T| - 1}{|T|^2}
\]

Substituting (6) into (3) and simplifying,

\[
\text{DOS}(s) = 1 - \frac{|T| \sum_{t \in T} (\text{CONC}(s, t) - \frac{1}{|T|})^2}{|T|^2}
\]

Using the validation methodology and terminology specified by Kitchenham, Pfleeger, and Fenton [43], DOS, and by extension DOSC and DOSM, has the following properties:

- It is normalized to be between 0 (completely localized) and 1 (completely delocalized; uniformly distributed) (inclusive) so that concerns can be meaningfully compared. DOS can theoretically take on any real value within this range and is therefore continuous. DOS is undefined when \(|T| \leq 1\).
- DOS is proportional to the number of elements related to the concern, and inversely proportional to the concentration. That is, the less concentrated the concern is, the more scattered it is.
- DOS is a ratio-scale measure (0 means “no scattering”). Thus, it is meaningful to compare and rank concerns by their DOS values, and obtain the average DOS.
- While DOS is unitless, the individual components of the DOS equation do have units, specifically, the units are lines of code (LOCs), \( T \), and the structural unit of \( T \) (e.g., classes, methods). One can directly compare two DOS values only they are both obtained from DOS equations with identical units. This implies that it is not meaningful to directly compare DOS values for two different programs, or two different versions of the same program, when \( S \) or \( T \) is different.

### 3.2.3 Comparing DOSC and CDC

The difference between DOSC and CDC is illustrated in Figure 2. The pie charts show how the code related to the concern is distributed among four classes. In the first scenario, the implementation is evenly divided among the four classes (the worst case). In the second, the implementation is mostly localized. We compute DOSC as follows:

![Figure 2. Comparing DOSC and CDC for two different implementations of the same concern.](image-url)
EADDY ET AL.: DO CROSSCUTTING CONCERNS CAUSE DEFECTS?

4.1 Concern Selection

Selecting the right set of concerns to analyze is critical to ensure that our theory is applicable, our statistical analysis is valid, and our results are meaningful. However, our broad definitions for “concern” and “nonexecutable specification” imply an infinite number of concerns from which to choose. The context of our theory reduces the scope to actual concerns, i.e., there is evidence that the concerns provide the rationale for the implementation. For example, maintainability is not an actual concern if the developer did not consider it. This is important because our theory only explains defects when they are related to actual crosscutting concerns. This requirement was difficult to satisfy as most of the 75 open-source projects we considered did not have requirements documents.

Another criterion was that the set of concerns should provide a rationale for most of the code. This reduces sample bias since all concerns are considered, not just those that are crosscutting. Furthermore, to ensure our correlations were statistically significant, we required that the final concern set include at least 30 concerns [38, p. 64]. This is easily accomplished by making concerns more granular; however, at some point we must increase the granularity of the program elements assignable to the concerns or suffer a loss in precision. For example, associating a concern with an entire method when it is only related to a single statement inflates the concern’s size. Unfortunately, our concern and bug assignment tools, and time restrictions, limited us to field- and method-level granularity (e.g., we could not assign individual statements). We discuss how this limitation affects internal validity in Section 7.3.

The actual process of selecting concerns involved determining (1) the appropriate concern domain (e.g., the software requirements specification), (2) what constitutes a concern in that domain, including the concern granularity, and (3) the concern hierarchy. The final concern hierarchy is entered into a tool we built, called ConcernTagger, so that we may begin assigning program elements to the concerns. We give examples of concerns for the three case studies in Sections 5.1–5.3. We describe the tool and assignment procedure in the next section.

4.2 Concern Assignment

Concern assignment is the process of determining the relationship between a concern and a program element [6]. In our methodology, an analyst determines the relationship by examining a set of concern descriptions and the source code (see Figure 3). For our studies, the most relevant relationship between concerns and program elements would be based on a likely-to-contain-defect rule:

A program element is relevant to a concern if it is likely to harbor defects related to that concern.

In other words, if a bug is reported for a concern, the defect is likely to lie in one of these program elements. Obviously, this relationship is difficult, perhaps impossible, to establish with any certainty. Instead, we approximate this rule using the prune dependency rule created by Eaddy, Aho, and Murphy [17], which is easier to decide:

A program element is relevant to a concern if it should be removed, or otherwise altered, when the concern is pruned.

DOSC = 1 - \frac{14[(25 - \frac{1}{n})^2 + (25 - \frac{1}{n})^2 + (25 - \frac{1}{n})^2 + (25 - \frac{1}{n})^2]}{14-1}

In the second scenario, the DOSC value is

DOSC = 1 - \frac{14[(97 - \frac{1}{n})^2 + (97 - \frac{1}{n})^2 + (97 - \frac{1}{n})^2 + (97 - \frac{1}{n})^2]}{14-1} = 0.08

DOSC is close to 0, indicating the implementation is mostly localized. CDC cannot distinguish the two implementations, as evident by the value of 4 for both.

4 METHODOLOGY USED TO VALIDATE OUR THEORY

To validate our theory, we chose to undertake a series of case studies of open source Java programs. In particular, we looked for medium-size programs that had a clear set of software requirements and documented defects (the reasons for these criteria will become apparent in a moment). For the three programs we selected, we reverse engineered the concern–code mapping and the bug–code mapping. We then inferred the bug–concern mapping. After obtaining the three mappings, we were able to compute the metrics described in the previous section and measure the correlation between scattering and defects.

More formally, our methodology for obtaining the mappings consists of the following steps:

1) **Reverse engineer** the concern–code mapping: S and Cs (Section 4.1), and R (Section 4.2). This part of our methodology, depicted in Figure 3, is subjective. However, we defined assignment rules to improve the repeatability of our mappings and chose statistical methods designed to improve the reliability of our correlation results.

2) **Mine** the bug–code mapping: S is the set of bugs and R is automatically determined using bug fix data. This is depicted in Figure 5 and described in Section 4.4.

3) **Infer** the bug–concern mapping. Section 4.5 explains how we associate a bug with a concern if the concern’s implementation was modified to fix the bug (depicted in Figure 6).

Fig. 3. Associating concerns with program elements.
To properly interpret this rule, consider a software pruning scenario where a developer is removing a concern to reduce the footprint of a program, or otherwise tailor the program, for a particular environment. In this case, they want to remove as much code as possible, short of a redesign, and without affecting other concerns.

A benefit of the prune dependency rule is that the mapping can be directly obtained by actually removing each concern in turn and noting which elements require changes. However, this task is very labor-prone and was not feasible for the scale of the projects we studied. We therefore relied on a human analyst to estimate the mapping. Based on our experience assigning the concerns of five small- to medium-size projects (13–44 KLOCs) by hand, we believe a prune dependency is easier to estimate than other types of relationships (e.g., implements [50], contributes-to [25] [52]) and produces relevant results [17].

In this context, relevance is the extent to which the prune dependency mapping agrees with the likely-to-contain-defect mapping. Both rules will exclude "obviously" irrelevant program elements including methods shared by all concerns (e.g., the main function), general purpose methods (e.g., String.concat), and elements contained in system and generic libraries. On the other hand, a prune dependency assignment will include some elements that are unlikely to contain defects, e.g., field declarations and accessor methods.

Deciding if a prune dependency relationship exists requires human judgment and is therefore subject to human error. Fortunately, our statistical analysis method (Spearman's correlation) mitigates the impact of these measurement errors since it only considers the relative ordering of values, not the absolute values themselves. We revisit the issue of assignment error in Section 7.1.

The actual assignment of elements to concerns was done by two of the authors using an extension to ConcernMapper [55], a plug-in for the Eclipse[6] development environment, developed by Robillard, Manggala and Weigand-Warr. ConcernMapper allows the user to associate program elements with concerns via drag-and-drop, etc. Our extension to ConcernMapper, named ConcernTagger[7], further allows the user to create a hierarchy of concerns and obtain concern metrics and assignment cov-

---

3 Assume that disabling the concern using a flag, preprocessor macros, or code generation is not allowed.

4 If we knew the likely-to-contain-defect mapping, we would measure similarity directly using the Jaccard similarity metric [58], for example.

5 It is not necessary to consider elements contained in system and generic libraries because application-specific concerns generally do not provide a rationale for general-purpose code (a similar argument is made in [19]).

6 http://www.eclipse.org

7 http://www.cs.columbia.edu/~eaddy/concerntagger
The analyst carries out the concern assignment task by systematically inspecting each program element and deciding if the prune dependency rule applies to any of the concerns. In some cases this decision is easy, e.g., any field named “log” has a prune dependency on the logging concern. However, we found that the accuracy of the majority of the decisions hinged on how well the analyst understood the program. To aid program understanding, we relied on project documentation, source code comments, code navigation and search tools, change history comments, and in the case of the Rhino study, unit tests.

4.3 Ensuring Independence of Concern Metrics

Correlation and regression analysis can only be applied to concerns whose concern metrics are independent [37, pp. 114, 206]. As we mentioned, concerns may be organized in a containment hierarchy, in which case the observation below applies:

**Observation.** The program elements associated with a concern via the prune dependency rule must (at least) include the program elements associated with the concern’s descendants.

**Justification.** The prune dependency assignment rule states that a program element is associated with a concern if removing the concern would require modification or removal of the element. Therefore, when concerns are organized in a containment hierarchy, removing a parent concern implies that the parent’s descendants are also removed. Since removing the parent’s descendants requires modification or removal of the program elements associated with the descendants, it follows that the parent concern must also be associated with those elements.

Our concern metrics are derived from the program elements associated with a concern. The observation above implies that the concern metrics for a parent concern are dependent on those of its descendant concerns (i.e., the metrics are collinear). For example, the root concern has the largest size and bug count and is the most scattered*. Correlation and regression analysis is undefined when the metrics of the concerns are interdependent [22]. Therefore, although we assigned all the concerns, we only performed statistical analysis on sets of concerns where no two concerns were descendants of each other (specifically, leaf concerns). Restricting our analysis in this way does not introduce sample bias since the leaf concerns provide the rationale for most of the code, as our concern coverage statistics (discussed in Section 6) show.

4.4 Bug Assignment

As is typical, we did not have records of individual defects. Instead, we relied on records of bugs: bug reports stored in an issue tracking system (ITS) and bug fixes stored in a source code control system (SCCS) [56]. A bug is caused by one or more defects. For example, an end user might report a crash (i.e., a failure [34]) that is caused by multiple defects, whereas a developer might report access to an uninitialized variable (a single defect). To validate our theory, we approximate defect counts—which are not directly measurable, with bug counts—which are directly measurable, as we will soon see.

4.4.1 Associating Bugs with Bug Fixes

When a bug report is filed in the ITS, the bug is given a unique bug id. The open source projects we analyzed had publicly accessible issue tracking systems, so the filer could be a developer on the project or an end user (or both). If the bug is genuine, not a duplicate, and is caused by defects in one or more source files, a developer eventually fixes it, submits the updated files to SCCS along with a reason for the changes, and then changes the bug status to “fixed.” We use the term bug fix to refer to the set of lines in the source code—which may span multiple files—added, removed, or modified to fix a bug.

Common source code control systems typically record the changes made to source files in the form of one or more deltas. A delta provides a list of the lines added, removed, and modified, and the reason for the change (called the commit message). The SCCS systems used by the projects we studied were CVS [12] and Subversion [15]. For CVS, the unit of change described by a delta is a single file, so a fix may consist of multiple deltas. For Subversion, the unit of change can include multiple files, so a fix consists of one delta.

A common approach for associating bugs with program elements is to search for deltas whose commit messages include keywords such as “bug” or “fix” [51], or include strings that look like bug ids [16] [27] [57]. However, relying on this information alone is insufficient. For one project we studied, the ids in 87 (37%) of the commit messages referred to enhancements instead of bugs,
which would have inflated the bug counts for some concerns. This is easily prevented by using the issue tracking system to verify that ids refer to actual bugs. Of course, bugs identified by keywords instead of ids cannot be systematically verified using this approach.

Furthermore, it is common for a bug to be fixed incorrectly the first time [51], or be worked on in stages, requiring multiple updates to the same file [2]. This can result in the same bug being counted multiple times. Again, using bug ids helps us minimize noise since we only count unique bug ids.

Our approach for recognizing bug fixes is depicted in Figure 5 and described in detail by Śliwerski et al. [57], which is similar to the approaches used by Fischer et al. [27] and by Ćubranic et al. [16]:

A delta is called a "bug fix" and associated with a bug if the change reason refers to a valid bug id according to the issue tracking system.

For Bugzilla, a valid bug is an issue in the ITS with a resolution of "fixed," a status of "closed," "resolved," or "verified," and a severity that is not "enhancement." For Jira, the type must be "bug," the resolution must be "fixed," and the status must be "closed" or "resolved." We included bug fixes associated with any branch in the version database (not just the main branch).

Here are examples of commit messages from the projects we studied that our approach associates with a bug:

"NEW - bug 172515: Synchronizing queries with Bugzilla stuck when empty results. https://bugs.eclipse.org/bugs/show_bug.cgi?id=172515"

"Fix for 305323: Rhino fails to select the appropriate overloaded method."

"Fix for JIRA IBATIS-260: ‘Hash conflict with groupBy resultMaps’"

We required that the majority of bugs in the issue tracking system be traceable to bug fixes using this approach. This helps ensure that we do not miss bugs that should be assigned to program elements (false negatives) and that our correlation results are statistically significant. This turned out to be a very stringent requirement. Out of the 75 medium-size (less than 50 KLOCs) open source projects we considered for our case studies, very few followed the practice of including bug ids in commit messages. However, this requirement ensured that our defect counts would be sufficiently accurate for our purposes.

4.4.2 Associating Bugs with Program Elements

To decide if a bug is associated with a program element, we created the fixed-for-bug rule:

A program element is relevant to a bug if it was modified to fix the bug.

For the first case study (Mylyn–Bugzilla), the first author associated bugs with bug fixes, and then program elements, by hand. We realized that this procedure (depicted in Figure 5) could be easily automated, which would eliminate inconsistencies caused by human error. We created a plug-in for Eclipse, named BugTagger, which automatically associates bugs from a Bugzilla or Jira issue tracking system with methods, fields, and types, using change history from a CVS or Subversion database.

4.5 Automatically Assigning Bugs to Concerns

Once we have mapped concerns and bugs to program elements, it is trivial to automatically associate bugs with concerns:

A bug is associated with a concern if the bug occurs in the concern’s implementation, i.e., the intersection of the sets of program elements associated with the bug and the concern is nonempty.

This is depicted in Figure 6. Our underlying assumption is that it is reasonable to associate a bug with a concern if the source code associated with the concern must be changed to fix the bug. This echoes the approach that is common in the software engineering literature (for example, see El Eman et al. [22]), where a defect is assigned to a class if it occurs in the class’s implementation. The bug count for a concern is therefore the number of unique bugs associated with the concern.

Our bug–concern assignment methodology does not consider the similarity of the sets of program elements assigned to the concern and bug, other than requiring that at least one element is shared. We therefore make no claims about the strength of the association between a bug and a concern. For example, if all the program elements modified to fix a bug were associated with one concern, we would say that the bug was strongly associated with that concern. For the purposes of validating our theory, we only need to know how defective a concern is, and for this our bug–concern assignment rule is adequate.

5 Our Case Studies

Case studies in software engineering test theories and collect data through observation of a project in an unmodified setting [63]. In this section, we summarize the programs we studied, explain how we selected the concerns, and provide some example concerns. We required all

* To prevent bias, concern assignment was performed by a different author.
three projects to share the following characteristics

- **Open source** – Ensures our studies can be replicated. In addition, program understanding, which is required for concern assignment, is very difficult without access to the source code [6].
- **Written in Java** – Limitation imposed by our tooling.
- **Production quality** – Helps us to argue that our results generalize to an industrial setting.
- **Maintained by several people** – This is more representative of industrial projects. Furthermore, our theory has greater applicability to highly collaborative projects, where we suspect the adverse effects of scattering to be more evident.
- **Easily identifiable set of at least 30 relevant concerns** (see Section 4.1).
- **Publicly accessible issue tracking system** (see Section 4.4.1).
- **Majority of bugs are referenced consistently by id in commit messages** (see Section 4.4.1).

To improve the generalizability of our results, we purposely varied some context parameters, such as application domain and project size. Table 2 summarizes the high-level project differences.

### 5.1 Case Study #1: Mylyn–Bugzilla

Mylyn is a production-quality plug-in for the Eclipse development environment that enables a task-focused development methodology [39]. It was developed by a team of graduate students and professional developers in conjunction with one of the authors of this paper. Version 1.0.1 consists of 168,457 lines of Java code (LOCs) computed using the Unix `wc` command; however, we limited our analysis to two components: `bugzilla.core` and `bugzilla.ui`, totaling 56 classes, 427 methods, 457 fields, 13,649 lines of Java code. We refer to this subset as **Mylyn–Bugzilla**.

The requirements for Mylyn–Bugzilla were reverse engineered based on the “New and Noteworthy” section of the Mylyn web site and the personal experience of one of the authors with the development and usage of the components. We identified 28 of Mylyn's functional and non-functional requirements related to the `bugzilla.core` and `bugzilla.ui` components (i.e., requirement concerns). This is somewhat short of the 30 concern requirement we put forth in Section 4.1. We explain how this affected statistical significance in Section 6.1. The requirements were organized as a list so they were all leaf concerns. Example requirement concerns are “Convert query hits to tasks” and “Support search for duplicates.”

For Mylyn–Bugzilla, one author (heretofore referred to as “Author A”) manually assigned concerns to program elements using the procedure outlined in Section 4.2. To avoid potential bias, a different author (“Author B”) manually assigned bugs to program elements using the procedure explained in Section 4.4. As explained in Section 4.5, the assignment of bugs to concerns was completely automated for all the case studies.

### 5.2 Case Study #2: Rhino

Rhino is a JavaScript/ECMAScript interpreter and compiler. Rhino began life as an industrial project at Netscape and was then transitioned to open source. Due to its large user base and extensive test suite, Rhino has a healthy number of bugs in its bug database. Version 1.5R6 consists of 32,134 source lines of Java code (SLOCs), 138 types (classes, interfaces, and enums), 1870 methods, and 1399 fields (as reported by ConcernTagger).

Unlike the other case studies, Rhino implements a formal specification: *The ECMAScript Standard* [18]. Obviously, this specification provides a strong rationale for at least part of the source code of any program that claims to conform to the specification. It was therefore an obvious choice for the concern domain. Every normative section and subsection of the specification was considered a concern, resulting in a hierarchy of 480 concerns. However, to ensure our samples were independent (as explained in Section 4.3), we only performed statistical analysis on 357 mapped leaf concerns.

The screenshot of ConcernTagger in Figure 4 shows a portion of the Rhino concern hierarchy. The “7 Lexical Conventions” concern is visible, along with its subconcern “7.8 Literals,” which has the child leaf concern named “7.8.5 Regular Expression Literals.” Also visible are some of the program elements assigned to the Regular Expression Literals concern, which would need to be modified or removed if support for regular expression literals was removed. Please refer to [18] for detailed concern descriptions.

For Rhino, Author B manually assigned concerns to program elements, while BugTagger automatically assigned bugs as explained in Section 4.4.2.

### 5.3 Case Study #3: iBATIS

iBATIS is a popular object-relational mapping (O/RM)
tool for persisting Java objects in a relational database. The project was started by a single developer in 2001 and has since gathered a community of collaborators. The community currently includes 12 active developers, some with industrial experience. Version 2.3 consists of 13,314 source lines of Java code, 212 classes, 1844 methods, and 536 fields (as reported by ConcernTagger).

The iBATIS Developer’s Guide provides a good overview of functionality, but makes for a poor concern domain. One reason is that the guide was clearly written after iBATIS was implemented—it is a stretch to say that the guide provides a rationale for the implementation. Concerns cause implementation, not the other way around, and therefore concerns must precede the implementation in time. Furthermore, the concepts in the guide are clearly organized and presented in a way that guides learning, not implementation. We therefore constructed a mock requirements document based on the guide consisting of 183 requirement concerns organized in a hierarchy. Of these concerns, 132 were leaves. An example requirement concern is “Caching,” which has subconcerns “Class Caching,” “Request Caching disc,” and “Statement Caching.”

For iBATIS, Author B manually assigned concerns, while BugTagger automatically assigned bugs.

### 6 Empirical Results and Discussion

Table 3 shows the amount of source code covered by the selected concerns and bugs. The concern coverage for Mylyn–Bugzilla is relatively poor, considering that only 43% of the code is covered by the requirement concerns we reverse engineered. This is likely due to a lack of a complete set of requirements for the Mylyn–Bugzilla component. In contrast, the bug coverage is high (92%).

The concern coverage for Rhino is high (88%), confirming that the ECMAScript specification explained most of the code. The remaining 12% is dead code, general pur-

*a A program element is “mapped” if it is assigned to at least one concern.

*b Comments and whitespace are included for Mylyn–Bugzilla, but excluded for Rhino and iBATIS.

*c “All” means all concerns in the concern domain. “Mapped” means those concerns that were assigned to at least one program element.

*d “All” means all “fixed” bugs (non-enhancement issues) found in the issue tracking system on or before the version of the program we studied. “Mapped” means bugs mapped to at least one program element that is present in the version we studied.

Fig 7. Scatter plots of the concern metrics versus bug count for Rhino.
pose, or implements other concerns. For example, Rhino implements some nonstandard extensions to ECMA-Script, as well as the E4X and LiveConnect standards. The bug coverage was somewhat low (66%), probably because some bugs were mapped to program elements that were absent in the version of Rhino we studied (1.5R6), or were related to concerns other than the ones we analyzed (e.g., LiveConnect).

Among studies that map concerns manually and exhaustively—as opposed to the more common approach of only mapping a subset of the concerns or a portion of the code—Rhino is the largest and most comprehensive study that we know of.

We obtained 98% concern coverage for iBATIS, signifying that the developer’s guide we used to create the requirements described all the functionality. The bug coverage was somewhat low (53%), probably because of the issues already mentioned for Rhino. Low bug coverage is not necessarily bad, as we explain in Section 7.2.4.

6.1 Is Scattering Correlated with Defect Count?

Figure 7 shows the scatter plots for all the concern metrics versus bug count for the Rhino project. DOSC and DOSM appear to have a logarithmic relationship with bug count. CDC, CDO, and LOCC have a clear linear relationship with bug count. We therefore used Spearman’s rank-order correlation coefficient, which supports both linear and curvilinear relationships, and mitigates to a certain extent the unreliability of our measurements (we discuss this further in Section 7.1). Table 4 shows our correlation results for the three projects. Correlation coefficients range from -1.00 (a perfect negative correlation) to +1.00 (a perfect positive correlation). A coefficient of 0 means no correlation.

The Mylyn–Bugzilla results (see Table 4a) show that our degree of scattering metrics (DOSC and DOSM) are moderately correlated with bug count (.39 and .50), and the concern diffusion metrics (CDC and CDO) are strongly correlated (.57 and .61). These correlations were statistically significant at the 5% confidence level. In other words, there is a small (5%) probability that the relationship between the scattering metrics and bug count is coincidental. Thus, even though we obtained only 28 concerns for Mylyn–Bugzilla instead of 30 as prescribed in Section 4.1, our results are still statistically significant.

The correlations are stronger and more statistically significant for Rhino (see Table 4b). All scattering metrics (DOSM, DOSC, CDC, and CDO) have substantial correlation coefficients—ranging from .63 to .74—indicating a strong association with bug count. The probability that the association exists by chance is minute (less than 0.01%).

For iBATIS (see Table 4c) we see correlations of similar strength as Mylyn–Bugzilla. All scattering metrics have a nontrivial association with defects with correlation coefficients ranging from .29 for DOSM to .58 for CDC. Similar to Rhino, the probability that the association exists by chance is minute (less than 0.01%).

Taken together these results support our hypothesis:

**Concern scattering is correlated with defects.**

It is interesting to consider one of the crosscutting concerns revealed by our analysis. In Rhino, the requirement “10.1.4 - Scope Chain and Identifier Resolution” was the...
6.2 Correlations between the Scattering Metrics
From Table 4 (a-c) we observe that the scattering metrics are strongly correlated with each other. For example, for Rhino, CDC is almost perfectly correlated with DOSC (.96). This is expected since CDC and CDO are coarser versions of DOSC and DOSM. In addition, the member-level metrics were strongly correlated with their class-level counterparts. This is also expected since a class is only associated with a concern if at least one of its members is associated.

Although we were hoping to determine if it is more profitable to analyze scattering at the class or method level when correlating defects, our results were inconclusive. For Mylyn-Bugzilla and Rhino, method-level scattering (CDO) had the strongest correlation (.61 and .77, respectively), whereas for iBATIS, class-level scattering (CDC) was the strongest (.58).

By and large, CDC and CDO were more strongly correlated with defects than DOSC and DOSM. We were somewhat surprised by this result. We expected DOSC and DOSM to decidedly outperform CDC and CDO because we believe degree of scattering more faithfully quantifies the scattered nature of a concern. However, our results indicate that simply knowing the number of classes and methods involved in the implementation of a concern is sufficient. It may be that degree of scattering is more useful when concern assignment is performed at the level of statements (or below). For example, moving redundant code into a shared function reduces degree of scattering but is undetected by CDC and CDO.

6.3 Testing for the Confounding Effect of Size
For all the projects, the size of the concern implementation (LOCC) had the strongest or second strongest correlation with bug count (.77, .90, and .53). This is consistent with several other studies [8] [11] [33] that found strong correlations between size metrics and defects (although [23] found no correlation). This indicates that larger concerns have more defects. This also suggests that a refactoring that reduces scattering but increases concern size might actually increase defects.

Previous studies have found correlations between object-oriented metrics, such as the CK metrics [13], and fault-proneness. However, El Eman showed that after controlling for the confounding effect of size, the correlation disappeared [22]. The reason is that many object-oriented metrics are strongly correlated with size, and therefore serve as surrogates for size.

Looking at Table 4 (a-c) we see a strong correlation between the scattering metrics and size (LOCC). For example, for Rhino (Table 4b), the strength of the correlation between CDO and LOCC is very strong (.80). The reason is obvious if one considers that as more classes and methods become involved in a concern’s implementation (CDC and CDO), the number of lines (LOCC) grows. In fact, CDC and CDO cannot increase without a simultaneous increase in LOCC. DOSC and DOSM are not directly dependent on the number of lines associated with a concern, but rather on how those lines are distributed across classes and methods. There is, however, a significant correlation between these metrics and size, ranging from .38 to .68.

The strong correlation between all the scattering metrics and size, and between size and bug count, indicates that we must test for a confounding effect. For the sake of thoroughness, we performed two tests: step-wise regression analysis and principal component analysis.

6.3.1 Size Test #1: Step-Wise Regression Analysis
For step-wise regression analysis [37, pp. 263-264], we build a regression model that initially consists of the concern metric that has the single largest correlation with bug count. We then add metrics to the model based on their partial correlation with the metrics already in the model. With each new set of metrics, the model is evaluated and metrics that do not significantly contribute towards the statistical significance are removed so that, in
the end, the best set of metrics that explain the maximum possible variance is left. The amount of variance explained by a model is signified by the model's $R^2$ value [37, p. 229].

For completeness, we also include the Adjusted $R^2$ and Standard Error of Estimate values. Adjusted $R^2$ explains for any bias in the $R^2$ measure by taking into account the degrees of freedom of the predictor variables and the sample population. From Tables 5 and 6, we see that the Adjusted $R^2$ values are almost the same as the $R^2$ values, which indicates that the bias is absent from our models. Standard Error of Estimate (Std. Error) measures the deviation of the actual bug count from the bug count predicted by the model.

We can now state our test: If size explains all of the variance in bug count, we would not expect step-wise regression to include any of our scattering metrics. Table 5 shows our step-wise regression results for the three projects. Narrowing our focus to Mylyn–Bugzilla (Table 5a), we see that the step-wise regression completed after two steps. From the first step, we can see that the most significant metric is size (LOCC). The $R^2$ value of .73 means that we can explain 73.0% of the variance in bug count using size alone. The second step adds a scattering metric (CDC), which improves $R^2$ only slightly.

Shifting our attention to iBATIS (Table 5c), we find results similar to Mylyn–Bugzilla. While all the scattering metrics in the final model (Model #5) contribute to explaining the variance in bug count to some extent, size explains the most variance. This is to be expected. Our theory states that scattering is responsible for some—not all—of the defects in the program. We therefore expect that size explains most of the defects. The step-wise regression models for Mylyn–Bugzilla and iBATIS indicate that scattering explains some of the variance in bug count, which supports our hypothesis.

The step-wise regression results for Rhino (Table 5b) are strongly in favor of our hypothesis. As explained in Section 6.1, DOSC and DOSM have a clear logarithmic relationship with bug count for Rhino. Since step-wise regression expects a linear relationship, we first took the logarithm of these metrics, which explains the terms LogDOSC and LogDOSM in Table 5b. From the table we see that the regression terminated after three steps and that at each step, the metric that explains the most of the remaining variance was chosen. From the $R^2$ value we see that the model with scattering metrics LogDOSC, CDC, and LogDOSM explains 92.8% of the variance in bug count—size (LOCC) does not factor into the prediction at all.

In summary, step-wise regression analysis supports our hypothesis because it indicates that scattering explains some—and for Rhino, most—of the variance in bug count for the three projects we studied independent of size.

6.3.2 Size Test #2: Principal Component Analysis

Because the scattering metrics and LOCC are highly correlated amongst themselves, it is likely that the Spearman and step-wise regression models do not explain as much of the variance in bug count as the coefficients imply (i.e., they overfit the data). To overcome this collinearity, we used principal component analysis (PCA) [36]. With PCA, a small number of uncorrelated weighted combinations of metrics (that account for as much sample variance as possible) are generated, such that the transformed variables are independent. These weighted combinations of metrics are called principal components.

Running PCA on the metrics for the three projects resulted in the generation of the principal components shown in Table 6 (a-c), which account for greater than 95% of the sample variance. For Mylyn–Bugzilla (Table 6a), three components were generated. The first component explains the highest amount of variance; the second component explains the second highest, and so on. The first component weighs all the metrics highly—DOSC has a weighting of .70, DOSM has .80, etc. This indicates that the scattering metrics are significant contributors to explaining the variance in bug count. The results for Rhino (Table 6b) and iBATIS (Table 6c) are similar.

We then used the principal components to build a regression model for each project. From Table 7 below, we see that the models are highly accurate at predicting bug count—as indicated by the high $R^2$ values—further indicating the importance of the scattering metrics. The models are also statistically significant at the 99% confidence level.

From the step-wise regression analysis and PCA results we conclude that concern size is not the single dominating factor—the scattering metrics contribute towards explaining the variance in bug count, thus signifying their importance and reaffirming our hypothesis.

### 6.4 Do Crosscutting Concerns Cause Defects?

A correlation by itself does not imply causality [37, p. 213]. Isolating cause and effect is easier for controlled experiments than for correlation studies such as our own [38, pp. 80-81]. Kan outlines three criteria for causality that correlation studies must meet before making causality claims [38, pp. 80-81]. The first is that the cause must precede the effect. This is equivalent to saying that crosscutting concerns precede defects related to those concerns. In our theory, crosscutting first manifests itself in the concern implementation plan, which precedes the defects that are introduced during the implementation of that plan.

The second criterion is that a correlation must exist. The results of our three case studies indicate that a moderate to strong statistically significant correlation exists between scattering and defects.

Finally, the correlation must not be spurious. We argue that the correlation is not spurious because 1) there is a plausible reason (i.e., a theoretical justification) for the correlation to exist, 2) we verified that the scattering metrics are not surrogates for size, and 3) the correlation is not coincidental since we observed similar correlation results for three separate case studies.

This brings us back to our original question: Do crosscutting concerns cause defects? Our theory and the results of our studies suggest “yes.” Independent verification, in the form of empirical studies and controlled experiments, is needed before we can be confident that a causal relationship exists.

### 7 Threats to Internal Validity

#### 7.1 Concern Assignment Unreliability

Our concern metrics are unreliable because of the subjectivity inherent in our concern assignment methodology. This limits the consistency and repeatability of our measurements. Indeed, studies [45] [52] have shown disparities between concern assignments produced by different analysts. Unreliability can also reduce the strength and significance of the relationship between scattering and defects [21].

While automated assignment techniques [2] produce consistent results, we believe that the assignment produced by our interactive technique more accurately captures the rationale behind the code [17], which we need before we can apply our theory. Thus, we tolerate some loss in measurement reliability for improved relevance.

We compensated for this unreliability in two ways. First, we used a rank-order correlation (Spearman) that can tolerate unreliable measurements as long as the relative ordering (rank) of the measurements is correct [38, p. 78]. Comparing measurements by relative order instead of absolute value is consistent with how the concentration metric, upon which our degree of scattering metric is based, should be interpreted [62]. This implies that it is sufficient for the concern assignment to be a close approximation of the “correct” concern assignment.

Second, two of our studies had large sample sizes (N=357 and 132). The correlation results show a moderate to strong statistically significant relationship between scattering and defects for all three case studies, which we would not expect if the measurements were completely unreliable.

Our future work is to measure the reproducibility (variance across analysts), repeatability (variance across trials), and accuracy (variance with respect to a reference assignment, i.e., a gold standard) of our prune dependency assignment technique. We will then be able to properly compensate for measurement errors by incorporating error estimates into our regression model.

#### 7.2 Bug Assignment Errors

In the context of bug assignment a false positive means that a bug should not have been associated with a program element, and a false negative means a bug should have been associated with a program element (but was not). These false observations may perturb bug counts. Bug assignment errors fall into three categories:

1) Incorrect bug metadata.
2) Bugs mapped to the wrong elements.
3) Bugs mapped to “missing” elements.

##### 7.2.1 Incorrect Bug Metadata

Many of the Mylyn–Bugzilla bugs were clearly enhancements although they were not classified as such. This is an example of a Category 1 error.

##### 7.2.2 Bugs Mapped to the Wrong Elements

Category 2 errors can occur when a commit message is misleading. For example, a sequence of numbers may be mistaken for a valid bug id (Category 2a, false positive), or a bug id may be referenced coincidentally (Category 2b, false positive) or not at all (Category 2c, false negative). We eliminated Category 2a errors by validating all bug ids against the issue tracking system, which allowed us to eliminate 32 false positives for one project. By choosing projects that use bug ids in commit messages in a disciplined and consistent (and in the case of Mylyn–Bugzilla, completely automated) way, we believe there are no instances of Category 2b or 2c errors.

It is also possible that the real defect does not lie in the lines changed by the bug fix (Category 2d). For example, instead of fixing the defect (e.g., because it lies in a third-party library), a “workaround” is made to another part of the code so that the defect no longer manifests itself. This leads to a false positive and negative since the bug should be mapped to a completely different program element. We agree with Purushothaman and Perry, who concluded that detecting Category 2d errors would require more information than “is available or automatically inferable.” [51]

It is common for a bug fix to include modifications unrelated to the bug (Category 2e) [10] [21] [51], or fixes for
multiple bugs (Category 2f). To reduce Category 2e errors, we ignored insignificant changes such as changes to whitespace and comments. We also ignored bug fixes associated with the first version of a file. To avoid false positives due to Category 2f errors, we ignored bug fixes that referenced multiple bug ids.

For two case studies the bug assignment task was completely automated using BugTagger. This eliminates Category 2 errors caused by the inconsistencies inherent in a manual assignment and guarantees assignment repeatability. However, there is always the possibility that BugTagger is faulty. We used the Jaccard similarity metric \[ \text{Jaccard} \] to compare the bug assignment produced by BugTagger with the one we created by hand for Mylyn-Bugzilla, and found the Jaccard similarity was 0.87, indicating the assignments were very similar. On closer inspection, we found that many of the disagreements were due to human errors made during manual assignment, further vindicating our decision to mechanize.

7.2.3 Bugs Mapped to “Missing” Elements

Category 3 errors can occur when a bug is mapped to some methods and fields that were present at the time of the bug fix, but were subsequently removed or renamed. For Rhino, initially 37 bugs (21%) were mapped entirely to missing methods and fields, and therefore could not be associated with any concern. Our assignment technique uniquely identifies program elements by their signature (the fully qualified element name, and in the case of methods, the list of parameters). Therefore, we investigated the possibility that the element's signature had been changed, e.g., the element was renamed or the parameter list was modified. BugTagger automatically detects changes to the parameter list, e.g., \text{foo}(\text{int}, \text{int}) changed to \text{foo}(\text{float}, \text{float}); however, name changes were harder to detect automatically. We therefore tracked down name changes by hand and were able to halve the number of bugs that could not be mapped to any concern. To further reduce these errors, we would need a concern mapping for every revision—not just the latest.

We would like to point out that the studies we are aware of that analyze defects based on mining software repositories \[ 16 \] \[ 22 \] \[ 27 \] \[ 50 \] \[ 57 \] suffer from the same problems. We believe that our enumeration of the possible errors, and recommendations for avoiding them, will be a welcome contribution to this area of research.

7.2.4 Impact of Assignment Errors on Our Results

Ultimately, we care about the extent to which false bug-code assignments propagate to false bug-concern assignments, which will increase errors in our defect counts and correlations. Some bug assignment errors may be masked. For example, we may miss a program element that should have been assigned to the bug, but as long as another assigned program element causes the bug to be associated with the correct concern, the false negative is masked. False positives can be masked similarly.

A bug that is not associated with a concern is not necessarily a problem. For example, in Mylyn-Bugzilla, 9 of the 110 defects were mapped to methods or fields not covered by any concern. In most cases, this is not an issue since a program element may be related to a concern from a different concern domain (e.g., “resource deacquisition” is a programming concern rather than a requirement or design concern). However, it may also mean that some concerns were not accounted for, which can skew the measurements.

7.3 Assignment Aggregation Error

Our concern and bug assignment techniques aggregate at the member level the lines of code associated with the concern or defect. This loss in granularity makes our assignments less precise \[ 65 \]. For example, often \textit{sibling leaf concerns}\[ 16 \] in Rhino are implemented using switch statements.\[ 17 \] For instance, the parent concern “\textit{15.2.4 - Properties of Object Prototypes},” has the following child concerns:

\begin{itemize}
  \item 15.2.4.1 - constructor
  \item 15.2.4.2 - toString
  \item 15.2.4.3 - toLocaleString
  \item 15.2.4.4 - valueOf
\end{itemize}

In this case, even though each concern is really only associated with an individual case in the switch statement \[ 19 \], they will be assigned at the method level and will therefore have inflated concern sizes. Let us further suppose a bug is associated with one of the cases. The bug will also be assigned at the method level and will therefore inflate the bug counts for the concerns not associated with the case statement.

In addition to inflated sizes and bug counts, the metrics computed for the concern subset will be very similar. For the Rhino project, we found that the standard deviations for all the metrics were much lower for sibling leaf concern clusters than for the entire population of concerns. For example, the standard deviation of the bug count was 3.31 for sibling leaf concerns but 14.07 for the entire population.

It is hard to predict the impact that aggregation error has on our results. Aggregation error appears to be biased in favor of supporting our main hypothesis in the sense that the more scattered a concern is, the more methods contribute to its implementation, increasing the number of opportunities for aggregation error to inflate the concern size and defect count.

Despite this bias, we argue that eliminating aggregation error would not reverse our conclusions, for the following reason: It only occurs when method level assignment is not granular enough to faithfully represent the implementation of a concern. This is true for Rhino where concerns were very fine grained and switch statements were prevalent. However, this is not the case for Mylyn-Bugzilla and iBATIS. Since the correlations for all three studies were moderate to strong and statistically significant, we conclude that eliminating aggregation error would not reverse our conclusions.

\[ 16 \] Sibling leaf concerns have the same parent and no children.

\[ 17 \] Rhino inherits many of these quirks from the JavaScript interpreter it was based on, which was written in C. If Rhino had been written in Java from scratch, virtual methods might have been used instead of switch statements, which would have reduced aggregation error.
8 Threats to External Validity

External validity is the degree to which we can draw general conclusions from our results. As stated by Basili et al., drawing general conclusions from empirical studies in software engineering is difficult because any process depends to a large degree on a potentially large number of relevant context variables. For this reason we cannot assume that the results of a study generalize beyond the specific environment in which it was conducted [4]. El Emam concurs: “It is only when evidence is accumulated that a particular metric is valid across systems and across organizations can we draw general conclusions.” [21]

There are many possible sources of defects including the complexity of the problem domain, developer experience, mental and physical stress, tool support, etc. [21]. Our theory only attempts to explain a small portion of defects, namely, those caused by the complexity associated with implementing crosscutting concerns.

We expect that the programming language has a large impact on how scattered a concern’s implementation is. Because the programs we studied were written in Java, we cannot generalize our results to other programming languages. Interesting future work would be to compare Rhino with SpiderMonkey18, an implementation of ECMAScript written in C.

The open source projects we studied had many similarities to projects developed in industry including the use of change management systems, extensive test suites, and descriptive commit messages. Therefore, we expect our results to hold in an industrial setting for Java programs of similar size (13–44 KLOCs).

It is possible that the relationship between scattering and defects only holds for requirement concerns and not for concerns from other domains, such as the ones mentioned in Section 2.

9 Literature Review

9.1 Feature Location

The goal of feature location (or more generally, concern location) is to learn the how, where and why of software: How and where is a feature implemented? Why is the code implemented this way? In a study of the information needs of developers, Ko, DeLine, and Venolia concluded that the information most sought after—and most difficult to obtain—was “the intent behind existing code and code yet to be written” [44]. This information is essential for making changes correctly, yet is largely undocumented.

Researchers have employed a variety of automated techniques to recover links between concerns and code. Antoniol, Canfora, Casazza, and Lucia employed information retrieval (IR) to find the correspondence between requirements documents and identifiers and comments in the source code [2]. Zhao et al. augment IR results with branch-reserving call graph information to improve relevance [65]. Several researchers [20] [61] [62] have analyzed execution traces of the program to see which methods are called when a feature is invoked. Poshyany et al. showed that accuracy can be improved by combining static and dynamic analysis techniques [50].

Automation is essential for feature location to scale to large continuously evolving systems. However, the relevance of the concern–code mapping they produce is debatable. For example, links between concerns and code may be missed by IR techniques if meaningful identifier names are not used [50] [69], and by execution tracing techniques if features cannot be exercised completely and orthogonally [50].

While the mappings produced by these automated techniques are well suited for guiding program comprehension and maintenance activities, we felt they would not be sufficiently relevant for validating our theory. Furthermore, we sought to eliminate the possibility that deficiencies, mistakes, or biases in the assignment algorithm could skew our results. We therefore required all assignment decisions to be made by a human analyst using our interactive concern assignment tool, ConcernTagger, as explained in Section 4.2. Obviously, this limited the size of the programs we could analyze.

9.2 Empirical Studies of Crosscutting Concerns

Many researchers have studied the impact of crosscutting concerns on code quality. Most of the effort has concentrated on developing new internal metrics, or adapting existing ones, for quantifying crosscutting, and assessing the impact of modularizing crosscutting concerns using techniques such as aspect-oriented programming.

For example, some researchers [45] [52] [64] have created concern metrics that measure scattering in absolute terms (e.g., number of classes that contribute to the implementation of the concern). Garcia and colleagues used their concern diffusion metrics in several studies [25] [28] [30] to show that, in general, modularizing crosscutting concerns using aspect-oriented programming improves the separation of concerns. As explained in Section 3.3, we believe our degree of scattering metrics complement the concern diffusion metrics by providing a more fine-grained measurement of scattering.

We know of one study besides our own that correlates aspect- and concern-related metrics with external quality attributes. Bartsch and Harrison examined change history data for a set of aspects and found a statistically significant correlation between aspect coupling and maintenance effort [3]. Their metrics were different from ours (aspect coupling versus concern scattering), and their external quality indicator was different (effort versus defects). Whereas we investigated the impact of a crosscutting concern on code quality prior to refactoring using aspects, they looked at the impact after refactoring. A benefit of our scattering metrics is that they may help identify the crosscutting concerns that would benefit the most from refactoring.

9.3 Empirical Studies of Software Quality

In this section we discuss some of the earlier work related to investigations of using historical measures of complexity, code churn, pre-release defects, etc. as predictors of

18 http://www.mozilla.org/js/spidermonkey
software quality in large software systems.

Ostrand et al. [46] use file status information such as "new", "changed", and "unchanged" along with other explanatory variables such as lines of code, age, prior faults, etc. as predictors in a negative binomial regression equation to predict the number of faults in a multiple-release software system. The predictions made using their binomial regression model had high accuracy for faults found in both early and later stages of development [46]. Khoshgoftaar et al. [40] studied two consecutive releases of a large legacy system for telecommunications. The system contained over 38,000 procedures in 171 modules. Discriminant analysis identified fault-prone modules based on 16 static software product metrics with a type I and II classification rate of 21.7% and 19.1%, respectively, and an overall classification rate of 21.0%. Nagappan and Ball [49] investigated the use of a set of relative code churn measures in isolation as predictors of software defect density for the Windows Server 2003 system. Relative churn measures are normalized values of the various measures obtained during the measurement of churn. They found that relative code churn measures were strong statistically significant predictors of code quality. In contrast, Eick et al. found no correlation between code churn and code quality [19].

Several researchers have attempted to find a relationship between defects and internal product metrics, such as code churn [49], size metrics [11] [22] [23] [33], object-oriented metrics (e.g., the CK metrics [13]) [11] [22] [33], design metrics [11] and prerelease defects [7]. We add to this body of research by examining the relationship between concern metrics and defects.

10 Conclusion

This paper is the first to provide empirical evidence suggesting that crosscutting concerns cause defects. We examined the concerns of three small- to medium-size open-source Java projects and found that the more scattered the implementation of a concern is, the more likely it is to have defects. Moreover, this effect is evident independent of the size of the concern's implementation (in terms of lines of code).

This evidence, although preliminary, is important for several reasons. It adds credibility to the claims about the dangers of crosscutting concerns made by the aspect-oriented programming and programming language communities. By establishing a correlation between concern metrics and an external quality indicator—defects—we provide a stronger form of validation for these metrics than previous empirical studies that focused on internal quality indicators (e.g., [25], [28]).

We also proposed a theory that suggests why crosscutting concerns might cause defects, and described our concern model and metrics. These can serve as the foundation for future empirical work.

It is important to realize that the novelty of our experiment and the subjectivity inherent in our methodology limit the conclusions we can draw from our results. Further studies are needed before we can draw general conclusions about the relationship between scattering and defects. To facilitate this, we are working on automating our concern assignment technique, which is needed to make application of our metrics practical for large systems (greater than 50 KLOCs).

Several questions remain. Can we reduce the likelihood of defects by reducing crosscutting (assuming concern size does not increase)? Are crosscutting concerns a by-product of programming technology, developer aptitude, or the inherent complexity of the concern? What is the relationship between code churn and scattering? If a relationship exists, we can use code churn to help identify crosscutting concerns [10] and as a cost-effective surrogate for measuring scattering. When code churn levels are dangerously high, concern analysis may provide an explanation and an actionable plan for reducing churn (e.g., by modularizing the underlying crosscutting concerns).

11 Online Appendix

We invite researchers to replicate our case studies. Source code for the subject programs and our measurement tools, complete concern and bug lists, concern-code and bug-code mappings, and our results are available at http://www.cs.columbia.edu/~eaddy/concerntagger.

Acknowledgments

The authors are extremely grateful to the anonymous reviewers for their feedback and suggestions. This research was funded in part by the Natural Sciences and Engineering Research Council of Canada.
